Disease associated with Ross River virus infection is common in humans in Australia with an estimated 4800 cases per year, and much larger numbers during epidemics of the disease.[15] The horse is believed to be an amplifying host of the virus because experimentally infected horses can infect mosquitoes.[16] The disease in humans is characterized by mild pyrexia and constitutional signs initially, with subsequent development of a rash on the skin and oral lesions. Arthritis or arthralgia is common and affects primarily the wrists, knees, ankles and small joints of the extremities. These signs and symptoms can persist for 2–3 months, and the disease can relapse.

22.1.28 # RABIES

22.1.28.1 ## Synopsis

22.1.28.1.1 ### Etiology

Lyssavirus of family Rhabdoviridae

22.1.28.1.2 ### Epidemiology

Occurs in all farm animals worldwide except Australia and New Zealand. Major zoonoses. Transmitted by bites of infected animal. Many different wildlife are vectors depending on geographic location; vampire-bats in South America, foxes in Europe and North America, skunks in North America, mongoose in Africa, raccoon in the United States recently

22.1.28.1.3 ### Signs

Incubation period varies from 2 weeks to several months. *Cattle* – Paralytic form: bizarre mental behavior (yawning, bellowing), incoordination, decreased sensation of hindquarters, drooling saliva, recumbency, and death in 4–7 days. Furious form: hypersensitive, belligerent, then paralysis and death as in paralytic form. *Sheep* – Outbreaks common; sexual excitement, wool pulling, attacking, incoordination, and then paralysis. *Horses* – Abnormal postures, lameness or weakness, depression, ataxia, pharyngeal paralysis, recumbency, hyperesthesia, biting, loss of anal sphincter tone, death in 4–6 days. *Pigs* – Excitement, attack, twitching of nose, clonic convulsions, paralysis

22.1.28.1.4 ### Clinical pathology

No antemortem test

22.1.28.1.5 ### Lesions

Non-suppurative encephalomyelitis

22.1.28.1.6

Differential diagnosis list:

- *Cattle*: Lead poisoning, lactation tetany, hypovitaminosis-A, listerial meningoencephalitis, polioencephalomalacia, nervous acetonemia
- *Horse*: Viral encephalomyelitis, herpes viral paralysis, cerebrospinal nematodiasis, equine degenerative myeloencephalopathy, protozoal encephalomyelitis, neuritis of cauda equina, horsetail poisoning, Borna, Japanese encephalitis, botulism
- *Sheep*: Enterotoxemia, pregnancy toxemia, louping-ill, scrapie
- *Pig*: Pseudorabies, Teschen's disease, Glasser's disease, and other meningitides (*E. coli* and *Streptococcus suis*).

22.1.28.1.7

Diagnostic confirmation

Fluorescent antibody test of brain. Negri bodies histologically

22.1.28.1.8

Treatment

None. All rabies cases are fatal

22.1.28.1.9

Control

Prevention of exposure. Vaccination of domestic animals and wildlife. Quarantine and biosecurity to prevent entry of virus into country

1384

1385

22.1.28.2

ETIOLOGY

Rabies is associated with the rabies virus of the genus *Lyssavirus* of the family Rhabdoviridae.[1] The genus is composed of at least six genotypes.

It was recognized long ago that the strain of virus known as the ‘street’ rabies virus differed in some way from ‘fixed’ strains which had been cultivated for vaccine production (grown in cell culture or passaged through serial generations of laboratory animals). It is now known that t there are several strains of rabies virus, which are adapted to particular host species but remain infective for any warm-blooded mammal.[2]

22.1.28.3

EPIDEMIOLOGY

22.1.28.3.1

Occurrence

Rabies occurs in all warm-blooded animals.[1,3] The disease occurs in cattle, sheep, pigs, and horses in most countries, except the insular countries that exclude it by rigid quarantine measures or prohibition of the entry of dogs. However, the genus Lyssavirus can still cause surprises. In 1996 and 1998, two women died in Queensland, Australia, from infections with a newly discovered rabies-related virus (Australian bat lyssavirus).[4] In 2002, a man died in Scotland after contracting European bat lyssavirus rabies indicating that after a century of apparent freedom from rabies, the disease is now enzootic in the UK.[4]

22.1.28.3.1.1

South America, Latin America and the Caribbean

Rabies in cattle is a major economic and public health problem in South America, where vampire bat-transmitted rabies results in cyclic outbreaks. Bovine paralytic rabies is endemic in the tropical regions extending from northern Mexico, to northern Argentina, and on the island of Trinidad.[1] An outbreak in cattle in Guyana was associated with a large number of bats that had inhabited a culvert that was not cleaned regularly because of excessive rainfall.

22.1.28.3.1.2

Europe

In Europe, sylvatic rabies is a major problem where the **red fox** is the principal vector. The disease is still spreading from a focal point that developed in Poland in the mid-1930s. It is endemic in Yugoslavia and Turkey, and has spread westward to Germany, Denmark, Belgium, Czechoslovakia, Austria, Switzerland, and France. Spread continues at the rate of about 30–60 km (18–37 miles) per year and the threat to the United Kingdom increases each year. finland had been free of rabies since 1959, but in 1988 sylvatic rabies occurred with the raccoon dog as the vector. Monoclonal antibody indicated the virus was an Arctic-type strain possibly related to the red fox. France reported more than 2000 cases of rabid cattle between 1968 and 1982, and had more cases in sheep than in either dogs or cats during the same time period. In former East Germany, sheep were the second most frequent animal diagnosed with rabies after foxes.

Epidemiological studies of rabies in Lithuania from 1990 to 2000 found that rabies among wildlife comprised 54% with the majority of cases in foxes (27%), followed by raccoon dogs (21%).[5] The incidence of rabies in foxes and raccoon dogs increased over the period of study. Also, the number of humans attacked by domestic animals and wild animals has increased.

22.1.28.3.1.3

Africa

Rabies occurs in most countries in the African continent, but the reported incidence is surprisingly low for an area with such a high population of wild carnivores. The incidence of rabies, and the range of species involved, is increasing in Africa, and a number of wildlife hosts has been identified, including wild dogs, jackals and mongoose. Because of dislocation of civilian life, rabies in Zimbabwe has increased in prevalence and geographical distribution in recent years.

Rabies is now a very serious zoonotic disease in South Darfur, Sudan.[16]

22.1.28.3.1.4

South Africa

Over a 4-year period, of all the domestic animal rabies cases reported, cattle accounted for one-half of the rabies cases in South African domestic animals. The **mongoose** accounted for 70% of the wild animal cases reported.[7] Widespread distribution of the rabies virus occurs when the young mongooses are evicted from their parents' territory during the winter months, forcing them to scatter over a wide area. This increases the probability of domestic animals coming in contact with rabid animals.

22.1.28.3.1.5

Canada

The arctic fox variant of rabies invaded most of Canada south of 60°N and east of the Rocky Mountains in the early 1950s largely by the migration of **arctic foxes** into the populated areas.[8] It died out in most of that range, but persisted for over 40 years in southern Ontario with sporadic incursions into narrow adjacent strips in western Quebec and northern New York. The principal vectors were red foxes (*Vulpes vulpes*) and, to a lesser extent, striped skunks (*Mephitis mephitis*). During the period 1957 to 1989, Ontario experienced more animal rabies cases than any almost every North American jurisdiction almost every year, and over 95% of those cases were limited to the southernmost 10% of the province's land area.

A second major outbreak, involving **striped skunks**, progressed from North Dakota into the prairie provinces during the late 1950s and 1960s. In the 1990s, the endemic areas in Canada are southern Ontario, which accounts for 85% of the Canadian diagnoses, and the prairie provinces where rabies is endemic in skunks. In western Canada, the main reservoirs of the rabies virus are skunks, bats, and foxes.

In southern Ontario, Canada, the ecogeographic patterns of rabies indicate that townships could be aggregated into 12 rabies units or clusters.[9] The units had different behaviors in terms of species composition, persistence, and periodicity. The ratio of rabid skunks to rabid foxes varied between areas which may be due to seasonal factors and urban development. This information is useful for planning rabies control programs.

22.1.28.3.1.6

United States

Information on rabies surveillance in the United States is published annually by the Centers for Disease Control and Prevention.[10–14] From 1999 to 2003, more than 90% of cases occurred in wild animals, 6 to 9% in domestic animal species. The disease occurred in humans, raccoons, skunks, bats, foxes, cats, dogs, cattle, sheep and goats, horses and mules, mongoose, rodents and lagomorphs.

Most cases of rabies reported annually in the United States occur among three groups of carnivores: raccoons, skunks, foxes, and among bats.[15] However, between 1960 and 2000, a total of 2851 cases of rabies in 17 other carnivore taxa were reported to the Centers for Disease Control and Prevention, Atlanta, Georgia.[15] Three species of other carnivores (mongooses, coyotes, and bobcats accounted for 92% of the cases reported among other carnivorous mammals.

The most frequently reported rabid wildlife cases occurred in raccoons, skunks, bats, and foxes.[10] The relative contributions of those species continue to change in recent decades because of fluctuations in enzootics of rabies among animals infected with several distinct variants of the rabies virus.

During the past 30 years, rabies in domestic animals has steadily decreased in the United States, whereas annual occurrence in wild animals has increased. Wild animals accounted for 92% of all reported cases of rabies in 1995, a decrease from 1994. Raccoons were the most frequently reported rabid animal (50.3% of all animal cases),

followed by skunks (22.5%), bats (10.0%), foxes (6.5%) and other wild animals, including rodents and lagomorphs (2.7%). Domestic animals accounted for nearly 8% of all rabid animals in the United States in 1995. In recent years, the number of rabid cattle was equal to, or greater than, the number of rabid dogs. The incidence of rabies in horses is low compared to wildlife or domestic small animals but some yearly fluctuations occur.

1385
1386

In 1990, for the first time since surveillance began in 1950, the number of cases in raccoons exceeded that in skunks. Raccoon rabies spread from Florida to raccoons in Georgia, Alabama, South Carolina, and North Carolina by natural spread.[2] A separate focus in the northeastern States was caused by a translocation of raccoons from Florida, with legal permits to Virginia for restocking of hunting preserves.[2] From the index case in a raccoon in 1977, near the Virginia–West Virginia border, over the next 17 years, 20 000 cases of rabies were recorded in raccoons, and several thousand associated cases in domestic dogs and other animals. In Canada, the rabies virus isolates from rabies-positive raccoons from 1982 to 1994 were the same strains found in foxes and skunks in eastern Canada,[8] and is different from the 'Mid-Atlantic' strain found in raccoons in the eastern United States. Local dynamics of epidemics of rabies in raccoons in the United States can be predicted.[16]

Historically, in North America, the number of cases of rabies in skunks exceeded that in either raccoons or foxes. Endemic skunk rabies occurs mainly in four geographical regions: southern Ontario and Quebec and upper New York State; the north central United States and the Canadian provinces of Manitoba, Saskatchewan, and Alberta; California; and south central United States. Within these broad areas, the disease persists in enzootic foci and erupts every 6–8 years. Experimental studies suggest that the species specificity of endemic rabies is due to differences in the pathogenicity of variants of rabies virus. Skunk rabies peaks in the spring and early winter, which is probably a reflection of certain life history events within the skunk population.

The prevalence of rabies in bats in the United States is about 6%, and transmission to humans is rare even though sensational journalism has caused many people to consider bats as a serious threat to health. All of the confirmed cases of rabies in bats in Michigan in 1993 were associated with the big brown bat; in New York the prevalence in 1993 was 4.6% and nearly 90% of rabid bats were the common big brown bat. However, the silver-haired bat was associated with two human cases of rabies.

Trends in national surveillance for rabies among bats in the United States from 1993 to 2000 have consistently found a diffuse geographic pattern of rabies in bats throughout the continental United States.[17] Although spillover infection of bat variants of rabies among terrestrial animals such as dogs and cats are rare, these variants of rabies virus have been associated with 92% of the indigenously acquired human rabies infections in the United States since 1990.[11] Data from 37 states from 1993 to 2000 indicate an increased risk of rabies among certain groups of bat species was consistently found across season and most geographic regions of the US.[17] The Brazilian free-tailed, eastern pipistrelle, and the silver-haired bats, when considered as a single group, were more rabid more frequently than were other bat groups.

All warm-blooded animals, with the possible exception of opossums, are susceptible, and there is no variation in susceptibility with age; 1-day-old pigs have been affected. Variation in susceptibility between species is noticeable. Foxes, cotton rats, and coyotes are extremely susceptible; cattle, rabbits, and cats are highly susceptible; dogs, sheep, and goats are moderately susceptible; and opossums little if at all.

22.1.28.3.2

Distribution of virus variants

The *Lyssavirus* genus belongs to the Rhadoviridae family of the Mononegavirales order and includes unsegmented RNA viruses causing rabies encephalomyelitis. They are well fitted to vectors belonging to the orders Carnivora (flesh-eating mammals including skunks), and Chiroptera (the order which comprises all of the 178 genera in 16 families of bats). Seven genotypes have so far been delineated within the genus. These genotypes are divided into two immunopathologically and genetically distinct phylogroups. Phylogroup I includes two African genotypes: *Mokola virus*, which has been isolated from shrews and cats, although its reservoir remains unknown, and *Lagos bat virus*, which has been found mainly in frugivorous bats but also in an insectivorous bat. Phylogroup II has five genotypes: *Duvenhage virus* (Africa), *European bat lyssavirus I* (EBLV-1; Europe), EBLV-2 (Europe), *Australian bat lyssavirus* (Australia), and the classical *Rabies virus* (RABV, worldwide). Members of the genotypes *Duvenhage virus*, EBLV-1, and EBLV-2 are exclusively found in insectivorous bats, members of the genotype *Australian bat lyssavirus* are found in both insectivorous and frugivrorous bats, and member of the genotype RABV are found in carnivorous and American bats (insectivorous, frugivorous, and hematophagus). The fact that lyssaviruses are well

established in two ecologically distinct mammal orders may very likely be the consequence of successful host switching.

Analysis of 36 carnivoran and 17 chiropteran lyssavirus representing the main genotypes and variants strongly supports the hypothesis that host switching occurred in the history of the lyssaviruses. In fact, lyssaviruses evolved in chiroptera long before the emergence of carnivoran rabies, very likely following spillovers from bats.[18] Using dated isolates, the emergence of carnivoran rabies from chiropteran lyssaviruses is estimated to have occurred 888 to 1459 years ago.

In Europe, bat rabies is associated with two specific virus strains: European bat lyssavirus type 1 and European bat lyssavirus type 2. European bat lyssavirus type 1 isolates have been found in serotine bats in France.[19] European bat lyssavirus type 2 virus have now been found in Daubenton's bats in England and Scotland.[20]

In North America, variants of rabies virus are maintained in the wild by several terrestrial carnivore species, including raccoons, skunks, and a number of bat species.[21] Each antigenically and genetically distinct variant of the virus in mammalian species occurs in geographically discrete areas and is strongly associated with its reservoir species.[11] Within each area, a spillover of rabies into other species occurs, especially during epidemics. Temporal and spatial analysis of skunk and raccoon rabies in the eastern United States, indicated that epidemics in raccoons and skunks moved in a similar direction from 1990 to 2000. However, to date there is no evidence that the raccoon rabies virus variant is cycling independently in the skunk population of the eastern United States or that the variant has undergone any genetic adaptations among skunks.[21]

Within broad geographic regions, rabies infections in terrestrial mammals can be linked to distinct virus variants, identified by panels of monoclonal antibodies or by genetic analysis.[2] These analyses have demonstrated substantial differences between isolates from various parts of the world. Most outbreaks of rabies tend to be host species-specific. Each variant is maintained primarily by **intraspecific transmission** within a dominant reservoir, although spillover infection of other species may occur within the region. Geographic boundaries of the currently recognized reservoirs for rabies in terrestrial mammals have been established. Reservoirs for rabies virus are found worldwide. The virus is maintained at endemic and epidemic levels in a wide variety of 1386
Carnivora and Microchiroptera (bats) species. There are also antigenically similar rabies- 1387

like viruses, including the Makola virus, the Lagos bat virus, Duvenhage virus, European bat lyssavirus 1 and European bat lyssavirus 2 rabies, which are found principally in small mammals (rodents, insectivores, insectivorous or frugivorous bats). These strains appear to be limited in their geographical distribution to regions in Africa, unlike rabies virus which is distributed worldwide. The rabies-related viruses represent potential public and veterinary threats because of the lack of effective vaccines and the difficulties with diagnosis.

The geographic boundaries of the currently recognized reservoirs for rabies in terrestrial species in North America are as follows:

- Raccoons in the southeastern United States
- Red and arctic foxes in Alaska, resulting in spread across Canada as far east as Ontario, Quebec, and the New England states
- Striped skunks in California, the north central States, and the south central States
- Gray foxes in small reservoirs in Arizona
- Coyotes in south Texas as a result of spread from domestic dogs in a long-standing reservoir at the Texas–Mexico border.

The first reported occurrence of rabies in a human being infected with the raccoon rabies virus was from Virginia in 2002.[14]

In Ontario, wildlife rabies persists in two predominant species: the red fox and the striped skunk. Molecular epidemiology studies indicate that there is no host specificity, but rather there are very clear and consistent differences in the virus from distinct geographical regions. Such analyses will allow further epidemiological study of the behavior of the virus in different regions.

Overlying the disease in terrestrial mammals are multiple, independent reservoirs for rabies in several species of insectivorous bats. Distinct viral variants can be identified for different bat species, but geographical boundaries cannot be defined for rabies outbreaks in the highly mobile bat species.

Certain antigenic variants exist in nature against which conventional vaccines do not fully protect. In Canadian studies, two major antigenic groups can be distinguished among the rabies virus isolates examined. One group is found in Ontario, Quebec and

the Northwest Territories and is represented in the wild by endemic red fox and striped skunk rabies that originated in northern Canada. The second group is found in Manitoba where striped skunk rabies is endemic.

The epidemiology of rabies in Chile and the animal species which serve as rabies reservoirs have been examined.[22] None of Chilean isolates segregated with viruses from the terrestrial reservoirs. No non-rabies lyssaviruses were found, and the Chilean samples were not related to viruses of the sylvatic cycle maintained by the common vampire bat. The Brazilian free-tailed bat was identified as the reservoir for the rabies genetic variant most frequently isolated in Chile from 1977 to 1998. The close association of a group of rabies viruses obtained from a domestic dog, Brazilian free-tailed bats, and a red bat with viruses maintained by red bat species in North America implicated species of this genus as the possible reservoirs of this particular genetic variant in Chile.

In Trinidad, bovine rabies is common and is due to the bat type.[23]

22.1.28.3.3

Methods of transmission

The source of infection is always an infected animal, and the method of spread is almost always by the **bite** of an infected animal, although contamination of skin wounds by fresh saliva may result in infection. Not all bites from rabid animals result in infection because the virus is not always present in the saliva and may not gain entrance to the wound if the saliva is wiped from the teeth by clothing or the coat of the animal. The virus may appear in the milk of affected animals, but spread by this means is unlikely as infection. The rabies virus is relatively fragile, susceptible to most standard disinfectants, and dies in dried saliva in a few hours.

One of the most important parameters in rabies models is the transmission rate, or the number of susceptible animals infected by a diseased animal per unit of time. In a population of 19 raccoons feeding at a concentrated, common food source available during the summer in rural eastern Ontario, raccoons bite and are bitten an average of 0.99 to 1.28 times per hour, respectively.[24]

Because of the natural occurrence of rabies in animals in caves inhabited by infected insectivorous bats, inhalation as a route of infection came under suspicion. It is now accepted that interbat spread, and spread from bats to other species is principally by bites, but that infection by inhalation also occurs. That infection can occur by ingestion

has been put to use in devising systems of vaccinating wildlife by baiting them with virus-laden baits. This also has implications for epidemiological study generally. For example, attenuated viruses used in baits could be taken by other than the target species, thus creating an unexpected seropositive segment of the animal population. It is also considered likely that outbreaks occurring naturally amongst carnivores may originate by them eating bats that have died of rabies.

22.1.28.3.3.1

Animal vectors

Traditionally, the dog, and to a minor extent the cat, have been the main source animals. However, native fauna, including foxes, skunks, wolves, coyotes, vampire, insectivorous and fruit-eating bats, raccoons, mongoose, and squirrels provide the major source of infection in countries where domestic carnivora are well-controlled. In general, foxes are less dangerous than dogs, foxes tending to bite only one or two animals in a group, while dogs will often bite a large proportion of a herd or flock. Raccoons and skunks are major reservoir of rabies in North America.

Bats are the important species in which subclinical carriers occur. Multiplication of the virus without invasion of the nervous system is known to occur in fatty tissues in bats, and may be the basis of the ‘reservoiring’ mechanism in this species. Violent behavior is rare in rabid animals of this species, but has been observed. Bats represent a serious threat of spread of rabies because of their migratory habits. Most spread is within the species, but the threat to humans and animal species by bats cannot be completely disregarded. Although rodents can be infected with the rabies virus they are not thought to play any part in the epidemiology of rabies, either as multipliers or simply as physical carriers of the virus. Many of the viruses they carry are rabies-like rather than classical rabies.

Rabies has occurred in swine herds where the skunk population is high, where farms were settled from rough terrain resulting in considerable interface between wildlife and domestic animals, and in which the management system allows the pigs to run free on the premises. The disease has occurred in pigs reared in a closed feeder barn where access by wildlife was very unlikely.

There is a difference in role between vectors. For example, in Europe it is thought that foxes carry the infection into a new area, but other species disseminate it within an area.[25] Foxes are the principal vectors and, as in Canada, cattle are the principal receptors. In western Canada, the main reservoirs of infection are skunks, bats, and

foxes. This would have important consequences for control programs based on wildlife surveillance.

Domestic livestock like cattle are rarely a source of infection, although chance 1387
transmission to humans may occur if the mouth of a rabid animal is manipulated 1388
during treatment or examination. The virus may be present in the saliva for periods up to 5 days before signs are evident.

22.1.28.3.3.2

Seasonal spread

Spread of the disease is often seasonal, with the highest incidence in the late summer and autumn because of large-scale movements of wild animals at mating time and in pursuit of food. In Canada, the frequency of rabies infection in livestock populations increases in the fall when adolescent foxes mature, begin mating behavior, and travel over large areas.

22.1.28.3.3.3

Latent infection

Because of rapid developments in virological techniques, especially serological screening of animal populations to obtain presumptive diagnoses of the presence of a virus in the population, the question of latent infection and inapparent carriers of rabies has assumed some importance. The presence of rabies antibodies in animals in a supposed rabies-free area is likely to arouse concern. Inapparent carriers do occur in bats and there is some evidence that latent infections can occur in other species.

22.1.28.3.4

Zoonotic implications

The prime importance of rabies is its transmissibility to humans, with veterinarians being at special risk. European data indicate that by far the greatest proportion of humans requiring pretreatment for rabies have been exposed to a rabid domestic animal, not a wild one.[1,3]

Human rabies is extremely rare in countries where canine rabies is controlled by regular vaccination. In the United States, a total of 28 cases of human rabies occurred from 1980 to 1995. Most were due to viral variants associated with bats. Rates of post-exposure prophylaxis in developing countries are about 10 times higher than those in the United States, and rates of human rabies are approximately 100 times higher. According to the WHO, over 30 000 people die each year from rabies and more than 10 million undergo

post-exposure treatment, having been bitten by a rapid animal.[3] In 1987, according to surveillance conducted by the World Health Organization, dogs were responsible for 91% of all human rabies cases; cats, 2%; other domestic animals, 3%; bats, 2%; foxes, 1%; and all other wild animals, fewer than 1%. The disease is a major occupational hazard for veterinarians who should receive pre-exposure prophylaxis. Because horses will bite each other and their handlers, rabid horses that are aggressive pose a serious threat to humans.

There is a lack of general rabies knowledge among the public.[26] The laissez-faire attitude toward rabies by Americans causes instances of rabies exposure to be commonplace. A survey of middle school children in Texas found a lack of basic knowledge about rabies. Only 0.3% of children achieved a minimum score of 75% on a survey of knowledge about rabies.[26] Respondents lacked knowledge about the disease is transmitted, and less than one-third were even aware of rabies epidemic in southern Texas despite the fact that a rabies epidemic had been occurring in southern Texas for the previous 13 years. Even more astonishing was the finding that 80% knew of the risk of acquiring rabies from an unvaccinated pet buy 57% claimed to own unvaccinated pets.

Rabies is not of major economic importance in farm animals, although individual herds and flocks may suffer many fatalities. The disease in human has always been considered **fatal**. Since 1970, there have been reports of five patients said to have survived rabies encephalitis.[4] All patients had received some rabies vaccine before the onset of clinical signs but none had had rabies immunoglobulin.

A 15-year-old girl who developed rabies one month after being bitten by a bat survived following intensive medical therapy including induced coma while a native immune response matured, and treatment with ketamine, midazolam, ribarvirin, and amantadine.[27] Probable drug-related toxic effects included hemolysis, pancreatitis, acidosis, and hepatotoxicity. The patient was discharged to her home after 76 days, and at nearly 5 months after her initial hospitalization she was alert and communicative, but with choreoathetosis, dysarthria, and an unsteady gait.

Rabies in the Americas. Between 1993 and 2002, the number of human and canine rabies cases in the Americas Region fell by approximately 80%.[28] There were 39 human cases in 2002, 63% of them transmitted by dogs. Human rabies transmitted by wildlife, mostly by bats is a risk to inhabitants in many countries in the Region. This sharp

reduction is attributable mainly to the control measures implemented by the countries in the Region, such as mass vaccination of dogs and prophylactic treatment of people who have been exposed.

22.1.28.3.5

Economic importance

The economic costs of rabies in a country are associated with pet animal vaccinations, animal bite investigations, confinement and quarantine of domestic animals which bite humans or which are suspected of exposure to rabid animals, salaries of animal control officers, laboratory diagnosis, the costs of pre-exposure and post-exposure prophylaxis and treatment and consultation, public education, staff training and clerical costs.

The cost of the '**point infection control**' program as a response to raccoon rabies introduction in Ontario in 1999 was $363 000 (Cdn) or $500 Cdn/km^2. The costs were justified as by containing the spread of raccoon rabies, annual savings to Ontario are estimated at $8 to 12 million.[29] The reported associated costs in Ontario before raccoon rabies occurred were estimated at about $6 million annually, excluding pet vaccination costs.

22.1.28.4

PATHOGENESIS

Following the deep introduction of rabies virus by the bite of a rabid animal, initial virus multiplication occurs in striated muscle cells at the site. The neuromuscular spindles then provide an important site of virus entry into the nervous system. Entry into the nervous system may also occur at motor end plates. In the olfactory end organ in the nares, neuroepithelial cells are in direct contact with the body surface and these cells extend without interruption into the olfactory bulb of the brain. Following entry of the virus into nerve findings, there is invasion of the brain by passive movement of the virus within axons, first into the spinal cord then into the brain[1,4] The immune response during this phase of the infection is minimal and explains why neutralizing antibody and inflammatory infiltration are usually absent at the time of onset of encephalitic signs. Antibody titers reach substantial levels only in the terminal stages of the disease. Following entry of rabies virus to the central nervous system (CNS), usually in the spinal cord, an ascending wave of neuronal infection and neuronal dysfunction occurs.

The primary lesions produced are in the CNS, and spread from the site of infection occurs only by way of the peripheral nerves. This method of spread accounts for the extremely

variable incubation period, which varies to a large extent with the site of the bite. Bites on the head usually result in a shorter incubation period than bites on the extremities. The severity and the site of the lesions will govern to a large extent whether the clinical picture is primarily one of irritative or paralytic phenomena. The two extremes of the paralytic or dumb form and the furious form are accompanied by many cases that lie somewhere between the two. Gradually ascending paralysis of the hindquarters may be followed by severe signs of mania, which persist almost until death. Destruction of spinal neurons results in paralysis, but when the virus invades the brain, irritation of higher centers produces manias, excitement, and convulsions. Death is usually due to respiratory paralysis. The clinical signs of salivation, indigestion and pica, paralysis of bladder and anus, and increased libido all suggest involvement of the autonomic nervous system, including endocrine glands. At death, there are viral inclusions and particles in almost all neurons in the brain, spinal cord and ganglia, but none in the supportive cells of the CNS. Electron microscopic examination also shows the presence of the virus in the cornea, which it reaches centrifugally along the peripheral nerves.

1388

1389

Virus reaches the salivary glands and many other organs in the same way, but the highly infective nature of saliva arises from passage of the virus along the olfactory nerve to taste buds and other sensory end organs in the oropharynx, rather than from the salivary glands. Experimentally, infection of non-nervous tissues in skunks and foxes has been reproduced in the adrenal medulla, cornea, and nasal glands.[19] The virus may be found in milk, in some organs and in fetuses, but the virus cannot be demonstrated in the blood at any time.

Variations in the major manifestations as mania or paralysis may depend upon the source of the virus. Virus from vampire bats almost always causes the paralytic form. ‘fixed’ virus that has been modified by serial intracerebral passage causes ascending paralysis in contrast to ‘street’ virus, which more commonly causes the furious form. The site of infection and the size of the inoculum may also influence the clinical course. There is also geographical difference in the proportion of animals affected by the furious or paralytic form of the disease. In the Americas most cases are paralytic. In Africa and India most cases in farm animals are the furious form.

The disease is always fatal, but infrequently an experimentally infected animal shows clinical signs of the disease but recovers. There are two recent records of spontaneous recovery in man, and the occurrence of non-fatal rabies in all species has been reviewed. There appears to be no field occurrence in domestic animals of the finding in experimentally infected mice that some strains of virus invade only peripheral nerves and

spinal ganglia leaving a number of survivors with permanent nervous disability. The pathogenesis of recovery from rabies is important relative to vaccination and serological testing to determine the incidence and prevalence of the disease. The literature on the animal models used for the study of the pathogenesis and treatment of rabies has been reviewed.[1]

22.1.28.5 CLINICAL FINDINGS

22.1.28.5.1 Cattle and sheep

22.1.28.5.1.1 Cattle

Among farm animals, cattle are most commonly affected. The incubation period in naturally occurring cases is about 3 weeks, but varies from 2 weeks to several months in most species, although incubation periods of 5 and 6 months have been observed in cattle and dogs. In one large-scale outbreak in sheep, deaths occurred 17–111 days after exposure.

Experimentally, in cattle the average incubation period was 15 days and the average course of the disease was 3.7 days. Unvaccinated cattle had shorter incubation and clinical duration of disease than vaccinated cattle. Major clinical findings included excessive salivation (100%), behavioral change (100%), muzzle tremors (80%), vocalization (bellowing 70%), aggression, hyperesthesia and/or hyperexcitability (70%), and pharyngeal paralysis (60%). The furious form occurred in 70%.

In sheep, experimentally, the average incubation period was 10 days, and the average course of the disease was 3.25 days. Major clinical findings included muzzle and head tremors (80%), aggressiveness, hyperexcitability and hyperesthesia (80%), trismus (60%), salivation (60%), vocalization (60%), and recumbency (40%). The furious form occurred in 80% of sheep.

In the **paralytic form**, knuckling of the hind fetlocks, sagging and swaying of the hindquarters while walking, often deviation or flaccidity of the tail to one side, are common early signs. Decreased sensation usually accompanies this weakness and is one of the best diagnostic criteria in the detection of rabies. It is most evident over the hindquarters. Tenesmus, with paralysis of the anus, resulting in the sucking in and blowing out of air, usually occurs late in the incoordination stages just before the animal becomes recumbent. This is a characteristic finding but it may be transient or

absent. Drooling of saliva is one of the most constant findings. The **yawning movements** are more accurately described as voiceless attempts to bellow. When paralysis occurs, the animal becomes recumbent and unable to rise. Bulls in this stage often have paralysis of the penis. Death usually occurs 48 hours after recumbency develops and after a total course of 6–7 days. The paralytic form of rabies has been reproduced experimentally by the IM injection of brain tissue from naturally occurring cases of paralytic rabies (‘derriengue’) in cattle in Mexico.

In **furious rabies** the animal has a tense, alert appearance, is hypersensitive to sounds and movement, and is attracted to noise so that it may look intently or approach as though about to attack. In some cases, it will violently attack other animals or inanimate objects. These attacks are often badly directed and are impeded by the incoordination of gait. Frequently, loud bellowing is usual at this stage. The sound is characteristically hoarse and the actions are exaggerated. Sexual excitement is also common, bulls often attempting to mount inanimate objects. Multiple collections of semen for artificial insemination have been made during very short periods from bulls that later proved to be rabid. With this violent form of the disease the termination is characteristically sudden. Severe signs may be evident for 24–48 hours and the animal then collapses suddenly in a paralyzed state, dying usually within a few hours.

There is no consistent pattern in either the development or the range of signs. Body temperatures are usually normal but may be elevated to 39.5–40.5°C (103–105°F) in the early stages by muscular activity. Appetite varies also. Some animals do not eat or drink, although they may take food into the mouth. There is apparent inability to swallow. Others eat normally until the terminal stages. The course may vary from 1 to 6 days. So wide is the variation in clinical findings that any animal known to be exposed and showing signs of spinal cord or brain involvement should be considered rabid until proved otherwise.

22.1.28.5.1.2

Sheep

In **sheep**, rabies often occurs in a number of animals at one time due to the ease with which a number of sheep can be bitten by a dog or fox. Clinically, the picture is similar to that seen in cattle. The minority show sexual excitement, attacking humans or each other, and vigorous wool pulling; sudden falling after violent exertion, muscle tremor, and salivation are characteristic. Excessive bleating does not occur. Most sheep are

quiet and anorectic. Goats are commonly aggressive, and continuous bleating is common.

22.1.28.5.1.3

Horses

Most recorded cases in horses are lacking in distinctive nervous signs initially, but incline to the paralytic form of the disease. Experimentally, the average incubation period was 12 days and the average duration of disease was 5.5 days.[30] Unvaccinated animals had shorter incubation periods and duration of clinical disease. Muzzle tremors were the most frequently observed and most common initial signs. Other clinical findings included pharyngeal paresis (71%), ataxia or paresis (71%), and lethargy or somnolence (71%). The furious form occurred in 43% of cases, some of which began as the dumb form. The paralytic form was not observed.

1389 1390

In naturally occurring cases, the initial clinical findings may include abnormal postures, frequent whinnying, unexplained aggressiveness and kicking, biting, colic, sudden onset of lameness in one limb followed by recumbency the next day, high-stepping gait, ataxia, apparent blindness, and violent head-tossing. Lameness or weakness in one leg may be the first sign observed, but the usual pattern of development starts with lassitude, then passes to sternal recumbency and lateral recumbency, followed by paddling convulsions and terminal paralysis.

In a series of 21 confirmed cases in horses, the clinical findings at the time of initial examination included ataxia and paresis of the hindquarters (43%), lameness (24%), recumbency (14%), pharyngeal paralysis (10%), and colic (10%).[31] The major clinical findings observed over the course of hospitalization included recumbency (100%), hyperesthesia (81%), loss of tail and anal sphincter tone (57%), fever ~38.5°C (52%), and ataxia and paresis of the hindquarters (52%). Mean survival time after the onset of clinical signs was 4.47 days (range, 1–7 days). Clinical findings of the furious form of rabies, such as aggressiveness (biting), compulsive circling, and abnormal vocalization, were evident in only two horses. Supportive therapy, given to nine horses, had no effect on survival time and did not correlate with the detection of Negri bodies at necropsy. Horses developing the furious form show excitement, become vicious, and bite and kick. Their uncontrolled actions are often violent and dangerous and include blind changes, sudden falling and rolling and chewing of foreign material or their own skin. Hyperesthesia and muscular twitching of the hindlimbs followed by crouching and weakness are also recorded in the horse.

22.1.28.5.1.4

Pigs

Pigs manifest excitement and a tendency to attack, or dullness and incoordination. Affected sows show twitching of the nose, rapid chewing movements, excessive salivation, and clonic convulsions. They may walk backward. Terminally, there is paralysis and death occurs 12–48 hours after the onset of signs. The clinical findings in pigs are extremely variable, and individual cases may present in a variety of ways and only one or two of the classical findings may occur.

22.1.28.6

CLINICAL PATHOLOGY

No antemortem laboratory examination is of diagnostic value, but tests for lead on blood, urine, and feces may help to eliminate lead poisoning as a possible diagnosis. Virus neutralization tests are available, but the presence of antibodies is not diagnostic. Other available tests are passive hemagglutination, complement fixation, radioimmunoassay, and indirect fluorescent antibody staining. These are used to determine immune status rather than as a diagnostic aid. An ELISA is available for measurement of rabies-specific antibody in the sera of major domestic and wildlife reservoirs in North America.

22.1.28.7

NECROPSY FINDINGS

Confirmation of a diagnosis of rabies depends on careful laboratory examination of fresh brain. The recommended laboratory procedure includes the following three tests and it is recommended that at least two of them be used on all specimens.

- A fluorescent antibody test (**FAT**) on impression smears from the brain – current recommendations include sampling of the hippocampus, **medulla oblongata**, cerebellum or gasserian ganglion. However, a recent publication stipulates that the hippocampus and cerebellum are less desirable samples than the thalamus, pons, or medulla for the detection of viral antigen, and that the current sampling recommendations stem from the visibility of Negri bodies, rather than the true distribution of viral antigen.[32] An FAT can be completed in approximately 2 hours and is highly accurate when done routinely by experienced personnel. The reliability of FAT confirmed by the mouse inoculation test is over 99%.[14] Those specimens that are negative on FAT, and have contact with humans, are inoculated into experimental mice. The incubation period in mice before clinical signs are seen averages 11–12 days (range of 4–18 days), and death occurs in 7–21 days. The

mouse brain is harvested as soon as signs appear and is submitted to the same tests described above. Thus a positive result can be obtained as soon as 4–7 days after inoculation. Some mice must be left for the full 21 days because only a negative result at that time can give a complete negative to the test. A tissue culture infection test is now available, which allows demonstration of the virus in stained tissue culture cells within 4 days. This may replace the mouse inoculation test

- A dot **ELISA** is available for the detection of rabies antigen in animals.[33] It is rapid, simple, economical and, in comparison with the FAT, the agreement is 95%.

A **histological search** for Negri bodies in tissue sections with results available in 48 hours. Because of false-positive diagnoses the technique is in some disrepute. An **immunoperoxidase** test for rabies can be used on formalin-fixed, paraffin-embedded brain tissues of domestic animals and wild animals when fresh tissues are not available.[16,23] In some cases, the brain tissue may be negative for the rabies virus using standard diagnostic techniques but immunohistochemical tests may detect the presence of antigen.[20] A reverse transcriptase polymerase chain reaction test has been found of value in detecting rabies infection in decomposed brain samples that were negative by the direct fluorescent antibody test.[34]

The histopathologic changes of rabies infection include a non-suppurative encephalomyelitis and ganglioneuritis, with neuronal necrosis and the formation of glial nodules. Negri bodies are most commonly found in the Purkinje cells of the cerebellum in ruminants. Spongiform change has also been reported in the brain of a heifer infected with rabies virus.[35]

22.1.28.7.1

Samples for confirmation of diagnosis

- **Histology** – one half of midsagittally-sectioned brain, cervical spinal cord (including root ganglia), gasserian ganglion, parotid salivary gland (LM, IHC)
- **Virology** – one half of midsagittally-sectioned brain, cervical spinal cord (FAT, ISO, BIOASSAY).

Note the zoonotic potential of this organism when handling carcass and submitting specimens.

22.1.28.7.1.1

DIFFERENTIAL DIAGNOSIS

The diagnosis of rabies is one of the most difficult and important duties that a veterinarian is called upon to perform. Since in most cases there is a probability of human exposure, failure to recognize the disease may place human life in jeopardy. It is not even sufficient to say that if rabies occurs in the area one will classify every animal showing nervous signs as rabid, because nervous signs may not be evident for some days after the illness commences. In addition, many animals suffering from other diseases will be left untreated. The best policy is to handle all suspect animals with extreme care but continue to treat them for other diseases if such treatment appears to be indicated. If the animal is rabid, it will die and the diagnosis can then be confirmed by laboratory examination.

1390

1391

Several diseases are characterized by signs of abnormal mental state or paralysis, or a combination of both (see Table 22.1 for the horse; Table 32.3 for cattle). Rabies must be differentiated from the following common diseases affecting the nervous system, according to species:

22.1.28.7.1.1.1

Cattle and sheep

- Lead poisoning. In acute and subacute lead poisoning in cattle the clinical findings are similar to those of furious and dumb rabies. In acute lead poisoning, the common clinical findings are blindness, convulsions, champing of the jaws with the production of frothy saliva, and twitching of the eyelids and ears. In subacute lead poisoning in cattle there is blindness, stupor, head-pressing, grinding of the teeth, and almost no response to treatment. Rabid cattle are usually not blind, and signs of motor irritation such as convulsions and twitching of the facial muscles usually do not occur. However, there are signs of bizarre mental behavior, such as wild gazing, bellowing, yawning, attacking, and compulsive walking
- Lactation tetany occurs in lactating cattle on lush pasture in the spring during cold wet and windy weather, and is characterized by hyperesthesia, tremors, convulsions, recumbency, and rapid death
- Vitamin A deficiency occurs in groups of young cattle from 6 months to 18 months of age not receiving adequate carotene intake or vitamin A

supplementation and is characterized by blindness in the ocular form and episodes of tremors and convulsions

- Polioencephalomalacia in cattle and sheep is characterized by blindness, nystagmus, opisthotonos, and convulsions; bellowing, loss of sensation, and tenesmus do not occur
- Listeriosis in cattle and sheep is manifested by localizing signs of circling and facial nerve paralysis
- Enterotoxemia in sheep is usually confined to lambs on heavy carbohydrate diets
- Pregnancy toxemia is a disease of pregnant ewes and is readily differentiated by the presence of ketonuria
- Louping-ill in sheep is transmitted by insects, has a seasonal occurrence, and a localized geographical distribution.

22.1.28.7.1.1.2

Pigs

In pigs, rabies must be differentiated from pseudorabies, Teschen's disease, and involvement of the brain in several other diseases of the pigs, such as hog and African swine fever, meningitis associated with *Streptococcus suis* type II, *Haemophilus* spp., Glasser's disease, *Escherichia coli*, septicemia, and erysipelas.

22.1.28.7.1.1.3

Horses

In horses, rabies must be differentiated from several diseases of the nervous system (summarized in Table 22).

The most common include: viral encephalomyelitis, herpes virus myeloencephalopathy, cerebrospinal nematodiasis, equine degenerative myeloencephalopathy, equine protozoal myeloencephalitis, neuritis of the cauda equina, horsetail poisoning, Borna, Japanese encephalitis, botulism.

22.1.28.8

TREATMENT

No treatment should be attempted after clinical signs are evident. If the bite is seen, immediately after exposure, irrigation of the wound with 20% soft soap solution or a

solution of Zephiran may prevent the establishment of the infection. Immediate and thorough washing of all bite wounds and scratches with soap and water is perhaps the most effective measure for preventing rabies in veterinarians bitten by rabid animals. In experimental animals, simple local wound cleansing has been shown to markedly reduce the likelihood of rabies. Post-exposure vaccination is unlikely to be of value in animals, as death usually occurs before appreciable immunity has had time to develop. Euthanasia of suspect animals must be avoided, particularly if human exposure has occurred, since the development of the disease in the animals is necessary to establish a diagnosis. Antirabies serum may become available for animal treatment at some future date. **In some countries, cases of rabies in farm animals are notifiable to the animal health and disease regulatory bodies.**

22.1.28.9 CONTROL

The major goal of rabies control in domestic and wild animals is the reduction or elimination of human rabies. The most rational approach to reducing human rabies is to reduce the prevalence and incidence of disease in animals. In developed countries, this has been accomplished by vaccination of dogs and cats, leaving much rabies in wildlife to be controlled. In countries without wildlife reservoirs, such as the Philippines, it would be economically advantageous to eliminate dog rabies. In Africa, where the incidence of rabies as well as the range of species involved is increasing, there is a need to develop new and economical methods of vaccinating domestic animals.

Pre-exposure immunization for individuals, like veterinarians, who are at high risk to rabies, has been recommended by the World Health Organization, since it reduces risk and provides a more rapid anamnestic response, eliminating the need for human globulin should exposure occur. Rabies pre-exposure vaccination is now mandatory in many veterinary colleges. Despite some mild adverse reactions, immunization against rabies is an important prophylaxis measure well-accepted by veterinary students.

For farm animals, there are two useful control techniques: the **prevention of exposure** and **pre-exposure vaccination**.

22.1.28.9.1 Prevention of exposure to the virus

This can be achieved by controlling access of wildlife species which are likely to come into contact with the farm livestock in particular areas or through vaccination of the wildlife. Foxes accounted for a very large proportion (85% in Europe) of wildlife rabies,

and a control program aimed at reducing their population using poison or traps was attempted until the 1970s.[36] This method of population reduction failed to control outbreaks or reduce enzootic rabies.

Point infection control. To control the introduction of raccoon rabies in Ontario in 1999, 'point infection control' was used to control the epidemic.[29] This involves the use of three tactics: population reduction, trap-vaccinate-release, and oral vaccination with baits to control the spread of raccoon rabies. Some raccoons were captured and euthanized which resulted in an 83 to 91% reduction in the raccoon population in an area of 225 km^2 around the location of the three original cases of raccoon rabies. Raccoon density in the population reduction zones declined from 5.1 to 7.1 km^2 to 0.6 to 1.1 km^2 following control. Cats were also captured, vaccinated and released. Raboral V-RG oral rabies vaccine was distributed aerially to vaccinate free ranging raccoons. The point infection control program is considered to be highly successful and will continue to be used to contain isolated cases of raccoon rabies.[29]

22.1.28.9.2

Pre-exposure vaccination of humans

The most successful form of rabies prevention is pre-exposure vaccination. In human medicine, there are no reported cases of rabies deaths in anyone who has had pre-exposure vaccination followed by a booster vaccination if exposed.[4]

The Centers for Disease Control (CDC) and Prevention has published the recommendations of the Advisory Committee on Immunization Practices (ACIP) for human rabies prevention, which indicate that rabies pre-exposure vaccination should be offered to persons more likely to be exposed to rabies virus than the population of the United States at large.[37] The recommendations of the ACIP for pre-exposure prophylaxis and maintenance of a detectable antibody titer differ depending on the estimated degree of risk of exposure to the virus. Four risk categories have established: continuous; frequent; infrequent; and rare. The classification depends on factors such as the occupation of the individual and geography.[38]

With directed continuing education, common sense, first aid, and the availability of modern biological agents, human rabies is nearly always preventable.[1] Rabies pre-exposure vaccination is recommended for anyone at increased risk of exposure to rabies, including veterinarians, veterinary students who work in university veterinary teaching

1391
1392

hospitals, laboratory staff working with rabies, vaccine producers, animal and wildlife control personnel, and zoologists.

The standard pre-exposure regimen is three doses of vaccine IM or ID on days 0, 7, and 28 (or 21). A booster dose after 1 year increases and prolongs the antibody response.[4] This pre-exposure vaccination permits post-exposure vaccination to consist of two doses of vaccine on days 0, and 3 instead of 5 on days 0, 3, 7, 14, and 28 and avoids the need for postexposure of administration of human rabies immunoglobulin.

A large proportion of at-risk staff members working in veterinary clinics, animal shelters, and wildlife rehabilitation centers in a study area did not receive rabies pre-exposure vaccination according to the recommendations of the ACIP of the CDC.[37,38] Cost may be factor because many of these employees are commonly short-term, part-time, or volunteer workers.

22.1.28.9.3

Post-exposure vaccination of humans

Modern post-exposure treatment is highly successful if done adequately. Wound care with passive and active rabies immunization are essential especially after severe exposure. Post-exposure treatment is assumed to neutralize or inactivate virus while it is still in the wounds, before it gains access to the nervous system where it is protected from the immune system. Therefore, treatment after exposure to rabies virus is very urgent, even if the patient was bitten months before. Thorough washing of rabies-infected wounds with soap and water can increase survival by 50%.[3] However, this inexpensive, readily available treatment is omitted in most cases.

The World Health organization recommends a multi-site intradermal regimen of 0.1 mL of vaccine at eight sites on day 0, at four sites on day 7, and at one site each on days 28 and 90.[39]

Passive immunization with human rabies immunoglobulin lowers mortality after severe exposure.

22.1.28.9.4

Post-exposure vaccination of domestic animals

An effective post-exposure protocol for unvaccinated domestic animals exposed to rabies includes immediate vaccination against rabies, a strict isolation period of 90 days,

and administration of booster vaccinations during the third and eighth weeks of the isolation period.[40] The protocol has been effective in dogs, cats, cattle, and horses.[40]

22.1.28.9.5

Vaccination of domestic animals

A *Compendium of Animal Rabies Control* is published annually by the National Association of State Public Health Veterinarians, Inc. in the United States and Canada.[25] It provides recommendations for immunization procedures in domestic animals, the vaccines licensed and marketed in the United States. Detailed information is provided on pre-exposure vaccination, management of dogs and cats and livestock, post-exposure management, and control methods in wild animals. Such publications should be consulted when necessary. In general, for cattle, sheep, and horses the primary vaccination is given at 3 months of age and boosters given annually. Farm livestock in endemic areas where clinical cases of rabies occur commonly should be vaccinated.

In countries where vampire bats are a major vector for rabies in farm livestock, vaccination of livestock is necessary but in countries such as Argentina, vaccination does not support a cost benefit analysis.[41]

22.1.28.9.6

Vaccines

Almost all rabies vaccines for domestic animals are inactivated.[25] Inactivated tissue culture cell vaccines given to cattle result in neutralizing antibodies in 1 month after the primary vaccination. A booster given 1 year later increases the titers, which are detectable 1 year after the booster. A vaccine inactivated with binary-ethylenimine, and containing aluminum hydroxide adjuvant, provides excellent protection for up to 3 years and is very useful for the control of rabies in cattle in Latin America where the vampire bat is the main vector.

Vaccinal antibodies are present in the colostrum of vaccinated cows and it is recommended that, where cattle are vaccinated annually, calves be vaccinated at 4 months of age and again when 10 months of age. Calves from unvaccinated dams can be protected by vaccinating them at 17 days of age. Postvaccinal paralysis does not occur after its use.

A post-exposure vaccination protocol including immediate rabies vaccination, with a minimum of one booster vaccination prior to release from quarantine, and 90 days strict isolation, was 99.7% successful in unvaccinated cattle, horses, sheep, goats, and pigs.

22.1.28.9.7

Vaccination of wildlife

The literature on oral rabies vaccination of wild carnivores in the United States has been reviewed.[42] Mass oral vaccination of terrestrial wild animals is a rabies control method that is feasible, effective, and internationally accepted.[36,42,43] It is based on the concept of applied herd immunity. The vaccines are efficacious when fed as vaccine-baits. The factors affecting acceptance of baits for delivery of oral rabies vaccine to raccoons have been examined.[44]

The oral immunization of foxes has resulted in a substantial decrease in the number of rabies cases in Europe. As a result of oral vaccination of the red fox (*Vulpes vulpes*) against rabies, using hand and aerial distribution of vaccine-laden baits, the rabies virus has almost been completely eradicated from Western and Central Europe.[45] The same dramatic decrease occurred in southern Ontario, Canada. In most countries, vaccine baits were distributed twice yearly; during the spring (March to May) and autumn (September to October). Several European countries have become rabies-free: Belgium, Luxembourg, France, Italy, Switzerland, finland and the Netherlands.[43] With the European Union consisting of 25 countries from May 2004, all the scientific knowledge is available for establishing efficient and adapted oral vaccination programs aimed at eliminating terrestrial rabies from this area.

Progress has been made in applying oral rabies vaccination to contain and eliminate some strains of terrestrial rabies in North America.[42] Notable examples include near elimination of rabies from red foxes in southern Ontario. Containment and elimination of canine rabies coyotes from south Texas, containment and near elimination of raccoon rabies from Ohio, prevention of raccoon rabies spread through the Lake Champlain Valley in New York and across northern Vermont and New Hampshire, and reduced incidence of rabies where other oral rabies vaccination projects targeting raccoons have occurred. As of 2005, both Ontario and New Brunswick were free of raccoon rabies for greater than 10 months and 2 years, respectively, after implementation of ‘point infection control’ strategies[29] but continued surveillance is critical to monitor effectiveness.

Raboral V-RG is the only rabies vaccine licensed for use in the United States. It has not produced sufficient levels of population immunity in skunks in the wild at the current dose and V-RG may be less effective in skunks than other species. Skunks are a major contributor to rabies in North America with 38% of cases associated with the raccoon

variant of rabies virus involved skunks in 2001.[12] This has raised concerns about an independent maintenance cycle for raccoon rabies in skunks. The national rabies management goals of virus containment and elimination of will likely remain elusive until an oral vaccine is licensed that is immunogenic in all terrestrial rabies reservoir species. Skunk rabies virus, which has the broadest geographic distribution of all terrestrial rabies variants in the USA can currently be addressed only through local trap-vaccinate-release or population suppression programs.[42]

1392 1393

A satisfactory vaccine for oral mass vaccination of skunks has not yet been developed. Many experimental and commercial-produced live-modified or recombinant-based oral rabies virus vaccines have been tested in skunks with contradictory results. An oral modified live rabies virus Vaccine SAD B19, used in striped skunks was innocuous and may be safer and more effective in skunks after oral vaccination than previously considered.[46] An attenuated SAG-2 vaccine was efficacious in challenge studies in skunks and raccoons and may satisfy both safety and efficacy concerns for oral rabies vaccination of major North American rabies reservoirs.[47]

During the 1990s in the United States, oral vaccination programs concentrated upon raccoons, gray foxes, and coyote, with similar success. As a result, raccoon rabies has not spread west of its initial concentration in the eastern states, and grey fox rabies in contained in the west central Texas, and no recent cases of rabies have been reported in coyotes away from the Mexican border for several years. However, vaccination is not a panacea and should be considered as an important adjunct to traditional prevention and control techniques in human and veterinary medicine.

It is notable that no practical vaccination methods have been developed for bats.[36] Phylogenetic analyses of viruses from bats and carnivores suggest a historical basis for still existing viral origins due to interactions between these taxa. Thus the possibility for pathogen emergence resulting from transmission by rabid bats with subsequent perpetuation among other animals cannot be discounted easily on any continent. Vampire bats have been vaccinated IM, scarification, oral, or aerosol routes using a vaccina-rabies glycoprotein recombinant vaccine.[48] The highest antibody titers occurred in animals vaccinated by the IM and scarification routes. All animals vaccinated by the IM, scarification, and oral routes survived experimental challenge, except 1 of 8 receiving the aeosol vaccination died.

Most consistent progress was achieved and maintained where:

- Large coherent territories covering certain sized areas were treated simultaneously
- All areas of fox habitat were included by using both manual and aerial distribution
- Vaccination zones were progressively expanded towards the infected area
- At least two vaccinations were done
- The bait density was a certain minimum.

The vaccination will succeed in reducing or eradicating rabies only if a sufficient proportion of the target population can be immunized. Mathematical modeling techniques are now being tested to examine the population biology of rabies in wildlife species such as raccoons and skunks.[49] Mass immunization of foxes by aerial distribution of vaccine-baits containing liquid rabies vaccine was highly successful in controlling rabies in both urban and rural areas of Ontario.[36,42]

In 1989, the Ontario began a 5-year experiment to eliminate terrestrial rabies from a study area in the eastern end of southern Ontario.[50] Baits containing oral rabies vaccine were dropped annually in the area at a density of 20 baits/km^2 from 1989 to 1995. The experiment was successful in eliminating the arctic fox variant of rabies from the entire area. In the 1980s, an average of 235 rabid foxes per year were reported in the study area. Between 1993 and 2001, no cases were reported. Cases of fox rabies in other species also disappeared. In 1995, the last bovine and companion animal cases were reported and in 1996 the last rabid skunk occurred. Only bat variants of rabies were present until 1999, when the raccoon variant entered from New York.

22.1.28.9.8

Quarantine and biosecurity

The most effective method of preventing the entry of rabies into a country free of the disease is the imposition of a quarantine period of 4–6 months on all imported dogs. This system has successfully prevented the entry of the disease into island countries, but has obvious limitation in countries that have land borders. The occurrence of the disease in two dogs in the United Kingdom in 1969–1970 in which the incubation period appeared to last 7–9 months suggests that the more usual period of 6 months may give incomplete protection. Therefore, vaccination on two occasions with an inactivated vaccine while the animal is still in quarantine for 6 months is the current recommendation. To require a longer period of quarantine would encourage evasion of the law by smuggling. The

situation in the United Kingdom, and in any country where the disease does not occur, is a vexed one. It is possible to rely chiefly on quarantine and act swiftly to stamp the disease out if it occurs. The shock eradication program would include quarantine of, and vaccination in, a risk area, ring vaccination around it, and destruction of all wildlife. This procedure is likely to be adopted in countries where the risk is small, such as Australia. Where the risk is great, consideration must be given to mass vaccination of wildlife by baits, because wildlife are the cracks in the defense armor. The use of combined vaccines containing rabies vaccine in other vaccines used in dogs would be an effective and panic-free way of increasing the immune status of the pet population.

22.1.28.9.8.1

22.1.29 # PSEUDORABIES (AUJESZKY'S DISEASE)

22.1.29.1 ## Synopsis

22.1.29.1.1 ### Etiology

Aujeszky's disease virus (suid herpesvirus 1) (SHV-1)

22.1.29.1.2 ### Epidemiology

In pigs worldwide and major economic importance in swine-raising areas. High prevalence of infection; lower incidence of disease. Infected pig source of infection; latent infection is characteristic; spread occurs within herds, between herds, and due to infected carriers; long-distance aerosol transmission occurs from area to area; immunity follows infection or vaccination

22.1.29.1.3 ### Signs

Fever, incoordination, recumbency, convulsion and death in piglets. Coughing, nasal discharge, sneezing, and dyspnea in older growing pigs. In cattle and sheep, intense pruritus at site of bite, excitement, circling, convulsions, fever, recumbency, paralysis, and death in 48 hours or less

22.1.29.1.4 ### Clinical pathology

Serology for virus neutralizing antibodies. Detection of virus in tissues

22.1.29.1.5 ### Lesions

Viral encephalitis

22.1.29.1.6 ### Diagnostic confirmation

Detection of virus in tissues; serology; inclusion bodies in nervous tissue and respiratory tract

22.1.29.1.7 ### Differential diagnosis

Swine:

- Viral encephalomyelitis (Teschen disease)
- Rabies
- Streptococcal meningitis
- Hog cholera
- African swine fever
- Glasser's disease
- Septicemias (*Escherichia coli*, erysipelas, salmonella)

22.1.29.2 ## ETIOLOGY

Pseudorabies is associated with porcine herpesvirus-1, Aujeszky's disease virus, or pseudorabies virus, a member of the family of Herpesviridae, subfamily Alphaherpesvirinae. The biological functions of the virus in the pathogenicity, immunogenicity, and transmission of vaccine strains of the virus in pigs have been described and reviewed.[1]

22.1.29.3 ## EPIDEMIOLOGY

22.1.29.3.1 ### Occurrence

Pseudorabies primarily affects pigs and occurs incidentally in other species. Pseudorabies had a wide geographical distribution including the United States, Britain, Europe, North Africa, Asia, South America, New Zealand, and Ireland. Recently, many countries have achieved freedom from the disease and those that have not have started some form of control and eradication scheme.

Epidemiologic modeling of the herd-to-herd transmission of pseudorabies over a 20-year period in the United States concluded that, if there is no eradication program in place, the projected prevalence would be 43% in high-risk States, 22% in moderate-risk States, and 5% in low-risk States by 2012.[2] The current program of eradication projected 23% prevalence rate in high-risk States, 10% in moderate-risk States, and 1% in low-risk States. With an increase in expenditure for eradication programs of 25%, the respective prevalence rates by 2012 would be 14%, 3% and <0.3%. In Belgium the overall herd

prevalence was deemed to be 35%.[3] Many countries including Australia, Canada, and Norway are free of the infection.

Pseudorabies is primarily a disease of pigs, and naturally occurring cases in cattle and horses are rare and usually fatal. Cases in cattle occur only sporadically but a number of animals may be affected when cattle and pigs are commingled. An outbreak of clinical disease occurred in sheep in Northern Ireland after the sheep had been shorn and housed adjacent to pigs excreting the virus[4]; cats on the same farm were also affected. The disease has occurred in goats that have been housed with swine, and the virus has been isolated from horses with neurological disease.[5] Pseudorabies infection has been recorded in feral swine in Florida, and may undermine eradication efforts in domestic swine.[6]

22.1.29.3.2

Morbidity and case fatality

Typically, the disease spreads rapidly in infected herds over a period of 1–2 weeks and the acute stage of the outbreak lasts 1–2 months. In sucking pigs, the morbidity and mortality rates approach 100%, but in mature swine there may be no clinical signs, and affected animals usually recover. The highest morbidity occurs initially in unweaned piglets, but as the outbreak continues and piglets become passively immunized through the sow's colostrum, the major incidence may occur in weanlings.

In recent years there has also been an increase in the morbidity and case fatality rates in older pigs associated with the intensification of pig rearing and the dominance of more virulent strains.

22.1.29.3.3

Risk factors

22.1.29.3.3.1

Animal risk factors

The seroprevalence of infection varies widely between herds, and between breeding and finishing pigs within herds.[7] The most important animal risk factors of virus persistence are **herd size** and the **population density** of the sows in the herd.[8] Endemic infection is more likely in herds of breeding sows with more than 66 sows. In Belgium, when testing 720 herds, 40% of the herds with young sows were highly positive.[3] Herds over 70 sows were also more likely to be infected.[3] In breeding herds, spread of infection is positively associated with increasing size of the herd, having the

gilts in the same barn as the sows (gestation barn), and serological evidence of infection in the finishing pigs.[9] The seroprevalence of infection is low in quarantined breeding herds, which makes them prime candidates for elimination of the disease by test and removal.[10]

In the early period of a compulsory vaccination program with gI-deleted vaccines, in an area endemically infected with the disease, the seroprevalence of infected breeding females is higher in farrow–finish than farrow–feeder herds.[11] Mandatory vaccination is beneficial in both herds but the pattern is linear in farrow – feeder herds and curvilinear in farrow – finish herds, being more rapid in the early period of the program. In the farrow – finish herds, the odds of infected breeding females were associated positively with seropositivity in the finishing pigs of the herd and with the density of the pigs in the county in which the herd is located.[11] In Belgium the presence of finishing pigs in the same herd increased the chances of being infected.[3] The spread and transmission of the virus between herds can be reduced by a reduction in the contact rate between the herds and their size and by a reduction of the transmission within the herd.[12]

1394
1395

The factors associated with circulation of the virus within herds include:

- Confinement of finishing pigs
- Concurrent infection with *Actinobacillus pleuropneumoniae*
- The length of time since the herd has been under quarantine
- The presence of clinical disease.

In general, pseudorabies does not increase the susceptibility of animals to infection with other pathogens.[7] In an experimental situation it has been shown that the virus is transmitted between vaccinated conventional pigs but not amongst vaccinated SPF pigs.[13]

The primary risk factors associated with seroprevalence of the virus in 500 swine herds in Illinois included **total confinement** and **density of infected herds** in the geographical area.[14] For counties with a high regional density of pseudorabies infection, the prevalence of infection within a county increased with increasing average herd size and increasing geographical density of swine herds in the county.[15]

In Minnesota, there was a high geographical density of pseudorabies infected herds within 5 km.[16] Similarly it was calculated than in Belgium if there were over 455 pigs/km^2 then there was a 10-fold increase in the risk of PRV.[3] Total confinement is associated with higher seroprevalence, presumably because of increased density of population and increased risk of transmission. In Pennsylvania, decreased density of pseudorabies-quarantined herds was associated with reduced risk of a herd becoming quarantined, whereas increased density of non-quarantined, uninfected herds was associated with a decreased probability of a herd becoming quarantined.[17] A farrow–finish herd was associated with increased probability of becoming quarantined, compared with being a feeder pig herd. Seroprevalence is higher in vaccinated herds, increases over the course of the eradication program, and decreases with an increased time between quarantine and the development of a herd plan.

In The Netherlands, the risk factors contributing to seroprevalence of infection in breeding herds included:

- Presence of finishing pigs
- Production type (producers of finishing pigs had a higher prevalence than producers of breeding stock)
- Vaccination of sows during nursing (in comparison to vaccinating all sows simultaneously at 5-month intervals, or vaccination during the second half of gestation)
- Pig density in the municipality where the herd was located (seroprevalence increased with higher pig density)
- Herd size of fewer than 100 sows
- Average within-herd parity (seroprevalence increased with higher within-herd parity)
- Replacement pigs raised on the premises
- Vaccine strain administered to the sows.[18]

22.1.29.3.3.2

Environmental risk factors

The survival capabilities of the virus under various environmental conditions influences the methods of transmission and control procedures.[19] The virus may survive for 2–7 weeks in an infected environment, dependent on temperature fluctuations and pH level, and for up to 5 weeks in meat. The stability of the virus suspended in aerosol under different conditions of temperature and relative humidity has been examined.[20] The infectivity of the virus in an aerosol decreases by 50% in 1 hour. Environments at 4°C supported the survival of the virus in aerosol better than at 22°C. The virus is lipophilic and sensitive to several commonly used disinfectants. Sodium hypochlorite (5.25%) is the most desirable and practical disinfectant. Suspensions of the virus in saline G solution and on the solid fomites, whole corn, and steel remained infectious for at least 7 days. Loam soil, straw, and concrete supported survival of the virus at 25°C for up to 1 week.[19] During shipment of pigs, bedding material and surfaces in contact with pigs may become contaminated. Rinsing a needle between sampling may reduce the probability of mechanically transmitting the disease.[21]

22.1.29.3.3.3

Pathogen factors

Field strains of the virus differ in virulence. Numerous genomically different strains of the virus exist, and restriction endonuclease (RE) analysis can distinguish between virus isolates, which is useful for identifying new isolates of the virus as they appear in pig populations.[22] A retrospective analysis of virus isolates from England and Wales over a 22-year period revealed considerable homogeneity of certain RE sites (*Bam*HI), both in number and size. The appearance of an isolate with a new DNA fragment in 1981 coincided with a marked increase in the number of outbreaks of disease.[22] A PCR assay was able to discriminate between the established strains and the new type. By relating this type to pig movement records it was possible to trace the spread of the new type virus which was isolated in 65% of the new outbreaks of pseudorabies in England and Wales in 1982.[22] In Denmark, restriction fragment analyses of older clinical isolates, and of isolates from all the virologically confirmed outbreaks since 1985, indicated the introduction of foreign strains. Strain variation in virulence has been observed in field isolates and produced by laboratory attenuation. The viral proteins that determine virulence of the virus have been described.[1] Some field strains

of the virus from Poland and Hungary have been identified by restriction fragment pattern analysis as derivatives of conventionally attenuated vaccine strains.[23] This is considered a rare event but must be considered in relation to trade in semen from vaccinated boars or trade in live animals between disease-free areas and areas where vaccination with live attenuated strains is practiced.

22.1.29.3.4

Methods of transmission

Pigs, and possibly rodents, appear to be the primary host for the virus. The virus is present in the nasal discharge and in the mouth of affected pigs on the first day of illness and for up to 17 days after infection.

22.1.29.3.4.1

Within herds

Transmission within herds occurs by direct oral–nasal contact between infected and susceptible pigs, and aerosols from projection of discharges during sneezing, but may also occur via contaminated drinking water and feed. Transmission within herds is independent of the size of the population.[24]

The spread of virus from infected animals to contact-exposed animals can be predicted using a reproduction ratio. The ratio of secondary cases to originally infected animals is called the basic reproduction ratio denoted as R_0. In the model, R_0 has a threshold property. When $R_0 > 1$, the infection can spread; when $R_0 < 1$, the infection will not spread and will disappear, and the animal population is effectively protected.[25] Experimentally, the quantification of vaccine-induced reduction in virus transmission indicates that vaccinating twice with a marker vaccine significantly reduced virus transmission. In unvaccinated groups, the R_0 was 10.0; in the vaccinated group the R_0 was 0.5.[26] Thus, it is possible to measure transmission experimentally.

The transmission of virus decreases rapidly following the start of a vaccination program[27] but extensive spread can still occur even among finishing pigs vaccinated twice.[28] Vaccinated pigs may shed more virulent virus than mildly virulent virus but there are no significant differences in magnitude of transmission.[29] Mixing of chronically infected pigs with seronegative pigs may not result in seroconversion in the seronegative pigs until a clinical outbreak of disease occurs.[30]

1395
1396

22.1.29.3.4.2

Between herds

Transmission between herds is due to introduction of infected animals, and the virus may still be introduced into vaccinated breeding herds.[31] Other methods of transmission of the virus into uninfected herds have been suggested, including farm laborers, vehicles, feedstuffs, rodents, and wild or domestic animals.

22.1.29.3.4.3

Within an area

Transmission within an area is a major problem and not well-understood. Spread is occurring across the United States despite an intensive eradication program.[16] Some evidence indicates that area spread may be associated with which swine market is used and the frequency of delivery of pigs to market per year.[32] In France it has been suggested that the presence of an infected herd within 1 km is an important factor in the spread of PRV.[33] The concurrent occurrence of an outbreak of disease on many farms in the same area in Denmark suggested long-distance airborne transmission of the virus.[32]

Infection is spread by **airborne transmission**.[34] Exposing pigs to aerosols of the virus results in respiratory and other clinical signs similar to field cases.[35] Sneezing probably generates the airborne virus. In a series of outbreaks in Britain between 1981–1982, seven of 11 were found to be likely to have been transmitted by aerosol on meteorological grounds.[36] Airborne spread occurred between herds 2–9 km apart. An epidemic in Denmark in 1987–1988, associated with foreign strains of the virus, suggests that airborne transmission occurred across the German–Danish border[34] especially as a southerly wind was blowing during the period of transmission. An epidemic occurred in 10 herds located within close proximity of each other in Indiana, and the clinical and meteorological data supported aerosol transmission of the virus.[37] An epidemic during the winter of 1987/88 was associated with an unusual predominance of southerly winds, supporting the hypothesis of airborne transmission of the disease.[32]

Computer modeling based on the mean dose of virus received by an animal at a farm downwind can be used to predict the airborne spread of the virus.[38] To test the hypothesis that the virus can be spread by aerosol, the application of a Gaussian diffusion model has been applied to an epidemic of pseudorabies in 10 herds located in

Indiana.[39] The epidemic spread through 10 farms across an area of 150 km. The county was free of infected herds for 2 years prior to the epidemic, which was well-documented. The transport of the virus was assumed to occur during the prepatent period from 3 to 7 days prior to the onset of clinical signs. Estimates of the virus dose received at a given barn indicate that transport of the virus was more efficient during the night than during the day. The low temperatures during the night resulted in decreased ventilation of the barn and greater cycling of air contaminated with the virus over the pigs.

The infection is transmitted in **feral swine** through the venereal route.[40] Following commingling of uninfected gilts with virus infected boars, the virus could be recovered from the reproductive tracts of the gilts and could not be recovered from the upper respiratory tract.

Virus is excreted in the milk of infected sows and in utero infection occurs. The virus is inactivated in meat after 35 days of storage at −18°C (0.5°F). Meat from infected pigs may cause infection when fed to dogs. Venereal transmission of latent infection in sows and boars has been suspected, but there is no direct evidence. The effects of pseudorabies infection in adult boars are related to the effects of the clinical disease rather than any direct effect on semen quality. The virus cannot usually be isolated from the urine or semen from infected boars, and therefore the preputial secretions and the ejaculate are unlikely vehicles for shedding of the virus.

22.1.29.3.4.4

Latency

Pigs that recover from infection are latent carriers of the virus for life. Reactivation, followed by shedding and spreading the virus, may occur following stress such as transport or farrowing, or by the administration of corticosteroids.[41,42] Serological testing of latent carriers detects the antibody response to the whole virus or to a pseudorabies virus glycoprotein.[43] During natural infection, the virus replicates at the site of infection, usually in the oronasal areas. The virus gains entry into the nerve endings and ascends by retrograde axonal transport, to the cell body in the trigeminal ganglion. Viral components can be found in both the trigeminal ganglion and the tonsils.[41] The tonsil is a primary site of virus replication and serves as an area for monitoring virus shedding during acute infection and reactivation. The virus can be isolated from tissue fragments of pigs clinically recovered from disease for up to 13 months and followed by a challenge with the live virus, which may be shed by sows

for up to 19 months after initial infection. Virus gene products can be found in the trigeminal ganglia and tonsils for many weeks following acute infection.[44] Latent infection can also occur in vaccinated pigs.

22.1.29.3.4.5

Other species

The rarity of spread to other species is due to the scanty nasal discharge and the improbability of the discharge coming into contact with abraded skin or nasal mucosa of animals other than pigs. The disease has occurred in sheep and cattle following the use of a multiple-dose syringe previously used in infected swine. The disease may spread from normal or clinically affected pigs to animals of other species, but does not usually spread between animals of the other species. For example, sheep and calves can be infected experimentally, but there is no evidence that they excrete the virus. The disease may occur in pigs, sheep, and cattle on the same farm. Brown rats may be a minor source of infection but are unlikely to be an important reservoir; they are capable of spreading the disease to dogs. The wild Norway rat is thought to have only a minor role in the transmission of the disease to farm animals. The virus causes fatal disease in dogs, which are usually infected from close association with infected pigs. The raccoon can be infected experimentally, but is not considered to be a long-term subclinical carrier of the virus. The possible role of wild animals in transmission of pseudorabies in swine has been examined with inconclusive results. It has been seen in Kodiak, Polar and Himalayan bears fed on a diet of raw pig's heads.[45] five viral isolates were recovered from latently infected wild boar originating from two regions of East Germany[46] but in the Netherlands the wild boar were said to be rarely affected.[47] The PRV infections in the wild boar in Germany are said to exist in the country as an endemic infection and persist completely separately to the domestic population and also do not appear to affect it.[48] The sacral ganglia and trigeminal ganglia of wild pigs were said to be a source of infection.[49] The latency was shown in 9/16 sacral ganglia, 7/16 trigeminal ganglia and 5/13 tonsils[49] from feral swine in the USA, but even so most of the transmission in feral swine is expected to be venereal. There seems to be little evidence of a high infection rate in the wild boar of the Netherlands but they are in contact with the wild boar of Germany.[50] It seems quite common in Spanish wild boar with 36% of a study of 78 being serologically positive. The wild boar strain is adapted to the wild boar pig.[51] A group 1 virus was isolated from a wild boar in 1993 and it was suggested that the virus persisted for several years in the wild boar population in Italy[52] and that the species should be considered a reservoir.[52] In Croatia

1396
1397

approximately 55% of tested wild boars were found to be seropositive.[53] The experimental infection of wild boars and domestic pigs with different strains has been carried out[51] and the clinical signs depended on the strain but the wild boar could infect the domestic strains and vice versa. The low virulence strains were highly adapted to the wild boar.

22.1.29.3.5

Immune mechanisms

When infected with a virulent strain of the virus, pigs develop an immune response that can completely, or almost completely, prevent the virus from replicating after the pig becomes reinfected.[1] Following natural infection, sows acquire immunity, which is transferred to their piglets in the colostrum and persists in the piglets until 5–7 weeks of age. Following intranasal challenge, piglets with colostral immunity from naturally infected sows are protected from clinical disease, but not against subclinical infection.

Vaccination of pigs with attenuated pseudorabies virus prevents clinical disease and death that may otherwise follow exposure to the virulent virus. Vaccination does not, however, prevent either acute or latent infection with virulent virus. As a consequence, vaccinated pigs, as well as non-vaccinated pigs that survive infection with the virulent virus, can become virus carriers and a source of the virus following reactivation of a latent infection. This is of vital importance in eradication programs wherein it is necessary to identify infected pigs regardless of their vaccination status. Maternal immunity interferes with inactivated virus vaccination much more than with live virus vaccination.[54]

Vaccination of pregnant sows induces a maternal immunity, which protects piglets from experimental disease. However, latent infection of young pigs with highly virulent virus can develop in the absence of clinical signs. The virus can reach the uterine and fetal tissues, via infected mononuclear cells, the presence of circulating antibodies induced on vaccination.[55] Vaccination of piglets before challenge exposure has little or no effect on the rate of establishment of virus latency, but vaccination does reduce shedding after subsequent experimental reactivation of the virus with dexamethasone. Attenuated thyrosine kinase-negative vaccine strains of the virus can also establish a reactivatable, latent infection.[56]

In growing and finishing pigs in quarantined herds, the serological status is unpredictable because the infection may continue to spread, may cease temporarily, or may cease

altogether. Evaluation of the serological status of the boars in a breeding herd does not accurately reflect the serostatus of the herd.

It has been suggested that the T cells are more important than the B cells in the clearance of PRV from the host[57] and it has been shown that strong T-cell mediated responses after challenge produce the best protection.[58]

22.1.29.3.6

Economic importance

The economic losses associated with pseudorabies in swine are due to clinical disease, and the costs of serological analysis and vaccination programs.[32] Because of the variability of expression of the infection in different herds, a description of a single farm's experience with pseudorabies is difficult to put into a larger perspective regarding the impact of disease at a state or national level.[59] Economic loss estimates must include the measurement of losses during and immediately after clinical outbreaks of disease, and the indirect losses incurred until after eradication of the disease. Losses have been estimated at US $25–50/sow per year; these include only losses during the period of the outbreak and the direct losses attributable to death and abortions. When expanding the observations of economic losses to 3 months after the termination of the outbreak, estimated losses may be as high as US $ 145/sow per year.[32] Economic analyses of the losses in a commercial farrow – finish herd of 240 breeding age sows in the United States revealed that the major part of the loss was caused by death of suckling pigs at 76% of total loss, nursery pig mortality accounted for 12.6% of total net loss, sow culling and deaths accounted for 9.4% of net loss, and market pig deaths accounted for 1.2% of net losses.[32]

The costs of eradicating pseudorabies vary depending on the methods employed.**Depopulation–repopulation** is the most expensive method because it requires culling of animals, clean-up costs, and downtime which represents the largest proportion of expense. In addition, the probability of reinfection following repopulation is a risk.**Test and removal** is the most inexpensive, and segregation of offspring is intermediate in costs. The cost of eradicating the virus from a swine herd can be in excess of US $ 220/inventoried sow; some estimates are much higher.[60] In large breeding herds or finishing herds with the continual influx of susceptible pigs, the disease may become endemic. Pseudorabies may also be a significant cause of reproductive inefficiency in pig herds, and infection within the herd may be initially manifest by abortions in the sow herd, followed later by the more typical occurrence of

neurological disease in suckling and growing pigs. The economic losses due to the disease can be very high because of mortality in young pigs, decreased reproductive performance, and the necessity to depopulate to eradicate the disease from a herd. An economic assessment of an epidemic of pseudorabies in a 150-sow farrow–finish operation on selected production and economic variables has been made. The mean litter size remained the same throughout the period of observation, but there was a two-fold increase in suckling pig mortality and 3.5-fold increase in stillbirths during the months of the epidemic compared with the period before the epidemic. Following the epidemic, suckling pig mortality was 14% greater and stillbirth rate was 71% greater than during the months preceding the outbreak. The major economic losses (88% of the total loss) were related to breeding herd removal/depopulation and production downtime.

22.1.29.4

PATHOGENESIS

The portal of entry is through abraded skin or via the intact nasal mucosa. The virus is pantropic and affects tissues derived from all embryonic layers. Receptor and receptor-binding virion proteins which can mediate the virus entry into the cell and cell to cell spread have been described.[61] The various glycoproteins of the virus are required for various stages of virion morphogenesis. For example deletion of glycoproteins gE, gI, and gM inhibits the virion maturation.[62] Pseudorabies glycoprotein gK is a virion structural component involved in virus release from the cell but not viral entry and its presence is important to prevent immediate reinfection.[63] Viremia occurs with localization of the virus in many viscera, but with multiplication occurring primarily in the upper respiratory tract. Spread to the brain occurs by way of the olfactory, glossopharyngeal, or trigeminal nerves i.e. via the autonomic nerves.[64] Cells with the common leukocyte antigen $CD45^{+}$ populate the CNS infected areas from the local capillaries and the number of cells is increased in proportion to the number of infected neurons.[65] Virus disappears from the brain by the 8th day, coinciding with the appearance of neutralizing antibody in the blood. When the virus gains entry through a skin abrasion, it quickly invades the local peripheral nerves, passing along them centripetally and causing damage to nerve cells. It is this form of progression that causes local pruritus in the early stages of the disease, and encephalomyelitis at a later stage when the virus has invaded the central nervous system. In pigs, pruritus does not develop after IM injection, but a local paralysis indicative of damage to low motor neurons occurs prior to invasion of the central nervous system in some pigs. In cattle, pruritus of the head and neck is usually associated with respiratory tract infection, while perianal pruritus is usually due to vaginal infection.

1397 1398

Inoculation of the virus into the nasal cavities or brain results in signs of encephalitis rather than local pruritus. With oral inoculation there is an initial stage of viral proliferation in the tonsillar mucosa, followed by systemic invasion, localization, and invasion of the central nervous system along peripheral and autonomic nerve trunks and fibers. Lesions of Auerbach's myenteric plexus and the skin may also occur.[66] The peripheral blood mononuclear cells, tonsil, lymph nodes and bone marrow are a poor source of virus after experimental infection.[67] The trigeminal ganglia and olfactory bulb are good sources of virus.[67] The virus may be present in the trigeminal ganglion of a naturally infected sow without any history of clinical disease. Experimental inoculation of the virus into young pigs can result in a mild pneumonia which may progress to a severe suppurative bronchopneumonia.[68]

The virus can invade the uterus and infect pre-implantation embryos, which can lead to degeneration of the embryo and reproductive failure.[69] Virulent pseudorabies virus can cause lesions in the uterine endothelium and ovarian corpora lutea of pigs in early pregnancy, and gene-deleted mutant virus vaccine given IV during estrus can cause ovarian lesions, which may affect fertility.[69] Through the use of embryo transfer procedures, infected embryos may disseminate the virus from donors to recipients.

22.1.29.5

CLINICAL FINDINGS

The incubation period in natural outbreaks is about one day.

22.1.29.5.1

Pigs

The major signs are referable to infection of the respiratory, nervous and reproductive systems. There is considerable variation in the clinical manifestation, depending on the virulence and tropism of the infecting strain. Nervous system disease is the major manifestation, but with some strains, respiratory disease may be the initial and prime presenting feature. There is also strain variation in the pattern of age susceptibility.

Young pigs a few days to a month old are most susceptible. Very young sucklings develop an indistinct syndrome, but prominent nervous signs occur in older piglets. A febrile reaction, with temperatures up to 41.5°C (107°F), occurs prior to the onset of nervous signs. Incoordination of the hindlimbs causing sideways progression is followed by recumbency, fine and coarse muscle tremors, and paddling movements. Lateral deviation of the head, frothing at the mouth, nystagmus, slight ocular discharge, and

convulsive episodes appear in a few animals. A snoring respiration with marked abdominal movement occurs in many, and vomiting and diarrhea in some affected pigs. Deaths occur about 12 hours after the first signs appear. In California, a consistent sign has been blindness due to extensive retinal degeneration.

In growing and adult pigs, the disease is much less severe but there is considerable variation depending upon the virulence of the infecting strain. In growing pigs, mortality falls with increasing age and is generally less than 5% in pigs at 4–6 months of age. With some strains, fever is a prominent sign, while depression, vomiting, and sometimes marked respiratory signs, including sneezing, nasal discharge, coughing, and severe dyspnea are common. Trembling, incoordination, and paralysis and convulsions follow, and precede death. With others, the disease may be manifest at this age by mild signs of posterior incoordination and leg weakness. Concurrent infection has been described with both PCV2 and ADV.[70] In adults, fever may not be present and the infection may cause only a mild syndrome of anorexia, dullness, agalactia, and constipation. However, virulent strains may produce acute disease in adults, characterized by fever, sneezing, nasal pruritus, vomition, incoordination and convulsions, and death. Infection in early pregnancy may result in embryonic death, or abortion, and early return to heat. An abundant vaginal discharge may occur. Infection in late pregnancy may result in abortion, or in the subsequent birth of mummified fetuses, which may involve all or only part of the litter. Abortion may result from the effects of fever or from viral infection of the fetus.

22.1.29.5.2

Cattle, sheep, and goats

There may be sudden death without obvious signs of illness. More commonly, there is intense, local pruritus with violent licking, chewing, and rubbing of the part. Itching may be localized to any part of the body surface, but is most common about the head, the flanks, or the feet, the sites most likely to be contaminated by virus. There is intense excitement during this stage, and convulsions and constant bellowing may occur. Maniacal behavior, circling, spasm of the diaphragm, and opisthotonos are often evident. A stage of paralysis follows in which salivation, respiratory distress, and ataxia occur. The temperature is usually increased, sometimes to as high as 41–41°C (106–107°F). final paralysis is followed by death in 6–48 hours after the first appearance of illness. A case of non-fatal pseudorabies in a cow is recorded. There is also a report of pseudorabies occurring in feedlot cattle in which there were nervous signs, bloat, and acute death, but no pruritus. In young calves, it is characterized clinically by

encephalitis, no pruritus, erosion in the oral cavity and esophagus, and a high case fatality rate. An outbreak in sheep was associated with skin abrasions acquired at shearing. Affected ewes were dull, inappetent, and had a fever of 41.1°C. About 23 of 29 affected sheep developed the 'mad itch', with nibbling of their fleece and frenzied attempts to bite one area of the skin and rub it against the wall and bars of their pen. Terminally, recumbency, tremors, and opisthotonos were common, and death occurred within 12–24 hours after onset.[4] five farm cats also became ill and died; the virus was isolated from the brain of one cat. In goats, rapid deaths, unrest, lying down and rising frequently, crying plaintively, profuse sweating, and spasms and paralysis terminally are characteristic. There may be no pruritus.

The clinical findings in dogs and cats are similar to those in cattle, with death occurring in about 24 hours.[9] In France, cases in dogs have been linked to strains of virus from wild boars.[71]

22.1.29.6 ## CLINICAL PATHOLOGY

22.1.29.6.1 ### Serology

The commonly used serological tests for pseudorabies-specific antibodies are the serum-neutralization (SN) and ELISA.

22.1.29.6.1.1 #### Serum neutralization test

The SN test using the Shope strain has been the 'gold standard' against which other serological tests are compared and has been most widely used because of its sensitivity and specificity. Specific virus-neutralizing antibodies are detectable in the serum of recovered pigs, and this test is in routine use for herd diagnosis and survey purposes. Antibody is detectable on the 7th day after infection, reaches a peak about the 35th day, and persists for many months. Paired serum samples taken as early as possible, and about 3 weeks later, show a marked antibody rise. However, the SN test lacks the sensitivity necessary for detection of pigs with low levels of humoral titers of specific SN antibodies which can be enhanced by using the Bartha gIII strain.[72]

1398 1399

Some herds may have no serological evidence of previous infection or current spread of the virus, but have single reactors in the herd which may be infected with the virus.[73] Such singleton reactors may be found in herds being monitored serologically for

presence of infection. These singleton reactors may be infected with strains of the virus that are relatively avirulent.

22.1.29.6.1.2

Enzyme-linked immunosorbent assay

The ELISA is more sensitive than the SN test, especially early in the immune response to pseudorabies antigens. However, because of its high sensitivity, screening ELISAs yield some false-positives which must be confirmed by another test, such as another ELISA, SN test or latex agglutination test.[74] False-positives are unlikely to be due to infection with other herpesviruses. ELISA has also been used as a meat juice test[75,76] with high sensitivity (93%) and specificity (98%). The indirect ELISA is a more rapid and convenient procedure, offering many advantages over the SN test for routine serodiagnostic work. An indirect ELISA, using whole blood collected onto paper discs, is a rapid and convenient test and eliminates the costs of using vacutainer tubes and separating the blood. An indirect ELISA based on recombinant and affinity-purified glycoprotein E of PRV to differentiate vaccinated from naturally infected animals has been developed.[77] An indirect ELISA has been developed in the Czech Republic[78] that can be used because of its high sensitivity and specificity for blood serum or frozen pork samples. It has allowed the demonstration of ADV in meat juice with only marginal titers in the blood. Commercial ELISA kits are available and some are more specific than others.[74] A highly sensitive and specific competitive ELISA based on baculovirus expressed pseudorabies virus glycoprotein gE and gI complex has been described.[79] This allows detection as early as 2 weeks post-infection and can handle large numbers of tests without the need to handle live virus.

In countries where vaccination is regularly used for control of the disease, an assay to serologically distinguish infected from vaccinated pigs is critical. While a vaccination program will reduce the circulation of virus in the field, it will not eliminate the virus from the pig population. To eradicate the virus, the ability to differentiate infected from vaccinated pigs is crucial. Several commercial ELISA kits can differentiate between vaccinated and naturally infected pigs.[80] Differentiation is possible when vaccine virus strains have either a natural, or a genetically engineered, deletion that encodes for either glycoprotein-I (gI), gIII, or gX genes. Commercial ELISA kits that specifically detect antibody responses to gI of the virus offer considerable advantages as diagnostic tests for the virus, with a sensitivity of 99.2% and specificity of 100%.[80] The gI ELISA is able to distinguish infected pigs from those vaccinated with gI-

negative vaccines[81,82] The field strains of the virus produce antibodies to gI when inoculated into pigs. Unvaccinated pigs, or pigs vaccinated with gI-negative vaccines, that become subclinically infected with field strains of the virus may be detected with the gI–ELISA for a long time after infection. Thus, pigs that are seropositive in the gI–ELISA have either been infected with the pseudorabies virus or have been vaccinated with gI-positive vaccines; gI-seronegative pigs can be considered to be uninfected. Eradication of the virus from swine herds is possible by gI–ELISA testing, and culling gI-seropositive pigs in herds using gI-negative vaccines.

Detection of pigs in the latent phase of infection can be done serologically.[43] Pigs of any age that survive the acute infection phase become latent carriers for life, and serologic testing consistently detects animals in the latent phase of infection if the test detects the antibody response to the whole virus or to a reliable pseudorabies-virus glycoprotein.[43] Of several serological tests examined, the glycoprotein-I and glycoprotein-III marker systems, which performed with similar sensitivity as the screening tests, were superior to the glycoprotein-X marker system in detecting antibodies in infected pigs.

22.1.29.6.1.3

Detection of virus

In infected pigs the virus is usually present in nasal secretions for up to 10 days. A common method for the diagnosis of pseudorabies in sows is to take swabs from the nasal mucosa and vagina. Polyester and wire swabs shipped in 199 tissue culture medium supplemented with 2% fetal bovine serum (FBS) buffered with 0.1% sodium bicarbonate and HEPES will yield optimum recovery of the virus. Wooden applicator sticks with cottonwool have antiviral activity and recovery of the virus may not be possible after 2 days, which is of practical importance if the samples are shipped by mail. The virus can be demonstrated in nasal cells by immunofluorescence and immunoperoxidase techniques.[83] The virus can be detected by direct filter hybridization of nasal and tonsillar specimens from live pigs.[44] The virus survives on tonsil swabs taken with Dacron-tipped applicators for up to 72 hours in cell culture medium under transport.[84]

New PCR techniques have been used[67] and have been used to differentiate between true and false serological positives when single reactor pigs have been found.[85]

22.1.29.7

NECROPSY FINDINGS

There are no gross lesions typical and constant for the disease, and diagnosis must rely on laboratory examination. When pruritus has occurred there is considerable damage to local areas of skin, and extensive subcutaneous edema. The lungs show congestion, edema, and some hemorrhages. Hemorrhages may be present under the endocardium and excess fluid is often present in the pericardial sac. In pigs, there are additional lesions of visceral involvement. Slight splenomegaly, meningitis, and excess pericardial fluid are observed, and there may be small necrotic foci in the spleen and liver. Foci of hepatic necrosis may also be seen in aborted fetuses. Histologically, in all species, there is severe and extensive neuronal damage in the spinal cord, paravertebral ganglia, and brain. Perivascular cuffing and focal necrosis are present in the gray matter, particularly in the cerebellar cortex. Intranuclear inclusion bodies occur infrequently in the degenerating neurons and astroglial cells, particularly in cerebral cortex in the pig. These inclusions are of considerable importance in differential diagnosis. Necrotizing lesions with inclusion-body formation in the upper respiratory tract and lungs is strongly suggestive of porcine pseudorabies. Ultrastructural observations have been made which included syncytia, cellular debris and macrophages and lymphocytes with vacuoles in their cytoplasm.[86] Virus may be detected by direct fluorescent antibody examination or by growth in tissue culture. The tissues of the head and neck regions of non-immune pigs yield virus most consistently and in the highest concentration after challenge. The immunoperoxidase test can be used to study the distribution of the virus in different tissues. Latent virus can be detected using a DNA hybridization dot blot assay. Where possible, whole carcasses and fetuses should be submitted for laboratory examination. The location of the optimal neural samples, including the paravertebral ganglia, has been described for sheep.[87] The placental lesions in pregnant sows that have aborted from natural infection with pseudorabies consist of necrotizing placentitis and the presence of intranuclear inclusions. In an experimental infection of loops of intestine it was shown[88] that there was necrosis of the follicles in the Peyer's patches and degeneration of the epithelial cells in the crypts and villi and degeneration of the cells in the myenteric plexuses. Intranuclear inclusion bodies were found 2–4 days after inoculation. The primary target of the wild ADV was the macrophages of the sub-epithelial area of the dome of the Peyer's patch.

1399 1400

22.1.29.7.1

Samples for confirmation of diagnosis

- **Histology** – one half of midsagittally-sectioned brain, spinal cord with paravertebral ganglia, Gasserian ganglion, placenta, liver, lung, spleen, tonsil, retropharyngeal lymph node (LM). Immunohistochemistry has been used to confirm rare cases in countries where the disease is rare[89] and other corroborating evidence is lacking.[90] Can also collect muscle samples for meat juice ELISAs[91]
- **Virology** – brain, spinal cord, liver, spleen, tonsil, retropharyngeal lymph node (FAT, ISO). CSF is not good for virus isolation.[67]

22.1.29.7.1.1

DIFFERENTIAL DIAGNOSIS

The different clinical forms of pseudorabies in pigs and ruminants resemble several diseases.

Teschen disease occurs in similar forms in certain areas; the diagnosis is dependent on serology and pathology.

Rabies is rare in pigs and is usually accompanied by pruritus at the site of the bite.

Streptococcal meningitis is restricted to sucking pigs of 2–6 weeks of age, the lesions are usually obvious at necropsy, and the causative organism is readily cultured from the meninges. The response to treatment with penicillin is good and is of value as a diagnostic test.

Encephalopathy associated with hog cholera, African swine fever, salmonellosis, Glasser's disease, *Escherichia coli* septicemia and erysipelas are considerations, and are usually obvious at necropsy.

Bowel edema causes typical edema of the head and eyelids, undo typical circumstances in weaner pigs and rapid death.

Salt poisoning causes typical intermittent nervous signs, with a typical history of water deprivation.

Respiratory form of pseudorabies should be considered in any outbreak of respiratory disease that is poorly responsive to usually effective therapeutic measures.

Reproductive inefficiency associated with enterovirus (SMEDI) and parvovirus infections closely resembles that associated with pseudorabies, and requires laboratory differentiation by virus isolation and serological testing.

In **cattle** the local pruritus is distinctive, but the disease may be confused with the nervous form of acetonemia in which paresthesia may lead to excitement. The rapid recovery that ordinarily occurs in this form of acetonemia is an important diagnostic point. The furious form of rabies and acute lead poisoning cause signs of mania, but pruritus does not occur.

22.1.29.8

TREATMENT

There is no treatment.

22.1.29.9

CONTROL

The control of pseudorabies is difficult and currently unreliable because normal healthy pigs may be infected and shed the virus for up to several months.

An important principle in control and eradication of the disease is the reproduction ratio, R_0, which is defined as the average number of new infections caused by one typical infectious animal. When $R_0 > 1$, the infection can spread; when $R_0 < 1$, the infection will disappear. In eradication programs it is essential that R be less than 1 and the infection will die out in the herd.

22.1.29.9.1

Strategies available

The methods of control or eradication include depopulation and repopulation, test and removal, segregation of progeny, and vaccination. The selection of a strategy for the control or elimination of the disease depends on the following:

1. Source of the herd infection
2. Method of transmission of the virus
3. Survival of the virus in the environment
4. Sensitivity and specificity of the diagnostic test

5. Risk factors in the herd,[92] which include:
    - type of operation
    - degree of herd isolation
    - prevalence of infection
    - value of the genetic material
    - level of management expertise
    - availability of suitable virus-free replacement swine if depopulation and repopulation is chosen as a strategy.

The eradication of the disease from small herds was described in Hungary.[93] In this country the shared use of boars, the pig density and the infection in the surrounding area were the most significant influences on the spread and control of the disease.

Breeding stock producers favor eradication, farrow–finish producers that do not sell breeding stock or feeder pigs are generally more concerned with the reduction of losses from clinical pseudorabies infection than with eradication. In the USA offsite all in/all out finishing was more frequent amongst the successful farms than the unsuccessful.[94] The unsuccessful also had other infected herds within 3.2 km (2 miles) and often no cleaning or disinfection.[94]

22.1.29.9.2

Economics of control and eradication

Depopulation–repopulation is the most expensive, segregation of progeny method is next, and the test and removal the most inexpensive per sow.[60] A computerized decision-tree analysis and simulation modeling can evaluate the economics of control and eradication strategies. The optimal alternative is to test and remove seropositive animals if the initial prevalence is ~57%; otherwise vaccination of sows only is preferred. Vaccination may be recommended at lower prevalence rates as a conservative approach. Eradication by test and removal combined with the use of gene-deleted vaccines is advantageous at any prevalence rate of infection.[95] Depopulation and repopulation is not the best option under any circumstances. Once formulated, a decision-tree analysis can be adapted to the prevailing economic or epidemiological conditions.

An epidemiological model projected future herd–herd disease transmission under alternative eradication or control programs over 20 years, from 1993 to 2012.[60] With current eradication program funding in the United States, the prevalence of infection would be 23% in high-risk states, 10% in moderate-risk states, and 1% in low-risk states. Increased funding for the eradication program would substantially reduce the prevalence of infection. Profitability for the average size farrow–finish herd was estimated to be US $ 6 per cwt of swine produced for virus-infected herds than for uninfected herds. Estimates of the value of economic welfare indicated that consumers would be the major beneficiaries of eradication because of reduced prices and increased consumption of pork.

In Sweden, it was estimated that an eradication program is economically viable.[96] The maximum benefits are derived where the Swedish agricultural sector is deregulated and consumers obtain about 50% of the benefits excluding program costs. In the current case where Sweden is a member of the European Union, the benefits are reduced mainly due to lower prices of inputs and pork.

An economic analysis of alternative control programs found that, for regions of high pig density, the most economical strategy is to lower herd prevalence by intensive vaccination before completing eradication by test-and-removal of remaining positive animals.[97] 1400 1401

Eradication and control programs used in France have been reviewed.[97] The eradication of PRV in a 170 sow herd was described[98] in which the affected animals were killed and the rest were then vaccinated and the total cost to the farm was about $50 000.

22.1.29.9.3

Determination of prevalence of infection

In large herds, the virus must be eliminated from the growing–finishing pigs and the breeding herd. Large herds that are virus-positive are infected in both groups; smaller herds are frequently infected in only the breeding herd.[99] An initial step in eradication is to determine the prevalence of infection. Representative samples of finishing pigs older than 4 months, and of breeding sows, gilts, and boars are tested. On the basis of the test results and the risk factors in the herd, a cost-effective plan can be devised for the individual herd.

22.1.29.9.3.1

Depopulation and repopulation

When the prevalence of infection in the herd is over 50%, eradication can be achieved by depopulation and repopulation with virus-free breeding stock. However, depopulation is the most expensive method and is not compatible with the retention of valuable pedigree stock. The entire herd is depopulated over a period of months as the animals reach market weight. After removal of the animals the entire premises are cleaned and disinfected. Repopulation should be delayed at least 30 days after the final disinfection, and swine should originate from a pseudorabies-free qualified herd and be isolated on the premises and retested 30 days after introduction. All herd additions should be isolated and tested 3 0 days after introduction.

22.1.29.9.3.2

Test and removal

The test and removal program is recommended when the prevalence of infection in the herd is below 50%. This method requires testing of the entire breeding herd and immediate removal of all seropositive animals; 30 days after removal of seropositive animals, the herd is retested, and if necessary at 30-day intervals, until the entire herd tests are negative. Following a second negative test, the testing regimen may be changed to test only 25% of the herd every 4 months. Seropositive animals are identified and culled. The test and removal method is superior to the vaccination system as a method of control. Valuable genetic material from breeding stock that are seropositive may be salvaged using embryo transfer techniques. Embryos may be transferred safely to susceptible recipient gilts from sows that have recovered from infection, but not from sows that are in the active stages of infection. The virus does not penetrate the outer covering of the embryo, but it can become attached to it so that it may physically transfer to the uterus of the recipient. This transfer of infection may occur if the donor sow is in the active phase of infection.

22.1.29.9.3.3

Offspring segregation

The objective of this strategy is to raise a pseudorabies-negative breeding herd to replace the infected herd. Once the herd is diagnosed as pseudorabies-infected, a regular schedule of vaccination is instituted. Gilts are vaccinated at first breeding, and both sows and gilts are vaccinated 2–4 weeks before farrowing to provide a high level of colostral immunity to their piglets. Offspring are removed at weaning and raised

apart from the infected herd. At 4 months of age, and then again before breeding, the segregated replacements are tested for antibody. Since colostral immunity is no longer detectable by 4 months of age, any animals over 4 months of age that are seropositive are considered pseudorabies infected. As the gilts reach reproductive maturity, the old sow herd is replaced. Segregation between the infected sow herd and the clean gilt herd is maintained until all positive sows have been removed and the facilities disinfected. Groups of seronegative pigs are identified and combined into larger groups to establish a new herd. The original herd is gradually depopulated, and the premises cleaned and disinfected. The new herd is then monitored on a regular basis.

22.1.29.9.4

Control programs in effect

Pseudorabies was first diagnosed in the North Island of New Zealand in 1976, an eradication program started in 1989 and the virus was cleared from the North island in 1997.[100]

A pseudorabies control program was introduced in England in 1983 when the infection was spreading rapidly. New legislation imposed restrictions on the movement of pigs where clinical signs of the disease were present in the herd. The first part of the eradication scheme involved testing all of those herds previously known to have pseudorabies. Within several months after the beginning of the eradication campaign, 417 herds had been slaughtered, involving 342 275 pigs, of which 72.5% were salvaged. Only 121 herds had been known to be previously infected, while the remaining 296 herds had been identified through tracebacks and reports of new cases. By 1985 it was concluded that the disease was well-controlled in England with only 10–14 infected herds remaining. Farmers were compensated for all animals slaughtered and also for consequential loss associated with the loss of stock. The cost of the eradication program was financed by a levy on all pigs normally marketed for slaughter in England. In 1995, England was free of Aujeszky's disease. Following the successful use of the gene deletion vaccination and eradication program the Netherlands is now free[101] and also Germany.[102] There were originally 70% seropositive sows in 1993, 1% in 1998 and now none (as above). In Sweden the herds were declared free from 12–53 months after the start of the programme.[103] Now In Northern Ireland, pseudorabies is more widespread than it ever was in Britain before the eradication program. Because the infection rate is over 50%, an eradication program based on slaughter of infected herds would destroy the swine industry. Thus the control program in Northern Ireland is based on the use of

vaccination, the culling of seropositive animals, and the gradual introduction of seronegative animals.

In the United States, the national pseudorabies eradication program was implemented in 1989 as a joint State – Federal–Industry-sponsored program.[104] Pilot projects were conducted in Iowa, Illinois, Pennsylvania, Wisconsin, and North Carolina from 1984 to 1987. In the pilot projects, 97.5% of 116 herds that were initially pseudorabies-positive were successfully cleared of infection. This indicated that eradication of pseudorabies virus from herds of swine can be efficiently achieved, and is most effective applied on an area basis. The introduction of the gene-deleted pseudorabies vaccines in the program was the technical breakthrough needed to be able to offer the national eradication program, since it was now possible to distinguish between naturally infected and vaccinated animals.[104] The program consisted of:

Stage I, preparation

Stage II, control

Stage III, mandatory herd clean-up

Stage IV, surveillance

Stage V, free.

In Ohio, the eradication has made progress and eradication is expected in 1996 at a minimum cost to the public and the process in Illinois has also been described.[105] In practice what it meant was that all were at stage I by 1991, stage II was in states with over 1% affected and stage III in the states with less than 1% affected, there were still 10 states in stage IV on 1/1/2000 but on the 1/1/2000 33 states were free and all were cleared by 2002. When an outbreak of the disease occurs in a susceptible herd the mortality may be very high, and the first consideration is to prevent spread to uninfected sows and litters and pregnant sows from infected pigs. They should be attended by separate personnel, or adequate barriers to mechanical transmission of infection should be arranged. On affected premises, cattle should be separated from pigs, and dogs and cats should be kept from the area. The affected herd should be quarantined, and all pigs sold off the farm should be for slaughter only.

22.1.29.9.5

Vaccines and vaccination

Vaccination is used to reduce clinical disease when outbreaks occur or when the disease is endemic in the herd. An effective immunity develops after natural infection or vaccination, and piglets from immune sows are protected from clinical disease during the nursing period by colostral immunity. **However, the presence of circulating antibody does not prevent infection, the development of latency and subsequent activation and excretion of the virus**. However, vaccination reduces viral shedding after natural infection. On farms in which the disease is endemic or outbreaks have occurred, vaccination of the sows, and management procedures to reduce the spread of infection, have markedly reduced preweaning mortality and reproductive failures. field studies in large numbers of herds where the sows were vaccinated three times annually show that the reproduction ratio was below 0.66, which is significantly below 1,[106] and massive spread of the virus does not occur.

It is often virtually impossible to prevent the spread of infection in a susceptible herd and vaccination of all pigs at risk, especially pregnant sows, is recommended. The vaccine reduces losses in infected herds, limits the spread of infection, and decreases the incidence in endemic areas. With a properly controlled and monitored vaccination and culling program in a breeding herd it is possible to control clinical disease and reduce the infection pressure. All breeding stock present during an outbreak are subsequently vaccinated regularly until they are all culled, which removes the major sources of virulent virus. Following this phase, newly introduced gilts and boars are tested, and monitored regularly. This is considered to be less costly than the test and slaughter policy.

However, in vaccinated herds, the virus continues to circulate and an accurate epidemiological analysis is not possible because titers caused by vaccination cannot be distinguished from those caused by natural infections.

Control of the diseases in many countries has always been based on compulsory intensive vaccination of the entire population.[102,107]

22.1.29.9.5.1

Vaccines

Conventional modified live virus and inactivated virus vaccines have been available. Both vaccines will reduce the incidence rate and severity of clinical disease

in an infected herd. They also reduce the field virus shedding and latency in the trigeminal ganglion after exposure to field virus.[108] The vaccine efficiency is however markedly influenced by the modified live virus vaccine strain and the route of administration. The vaccine genotype plays a very important role in the effectiveness of the vaccine program. Recently needle-free transdermal vaccination using a modified live PRV vaccine has been described thereby preventing the loss of any needles in the carcase.[109] Cell mediated immunity in the form of cytotoxic T-cells may play an important part in the effectiveness of the vaccine.[110] The deficiencies of inactivated vaccines in producing virus specific interferon gamma (IFN) can be enhanced by the use of simultaneous administration of IL-12 which appears to upregulate Th1/Th2 expression.[111]

22.1.29.9.5.2

Pregnant sows

Vaccination of pregnant sows induces SN antibodies, which are transferred to the newborn piglets and provide protection against infection. Vaccination during pregnancy produces more protection against PRV for piglets than sow vaccination before mating.[112] A better protection was observed in sows vaccinated with an attenuated virus than in sows vaccinated with inactivated virus.[113] Piglets rely on colostral and milk antibodies for protection, and the vaccination of piglets born from vaccinated sows does not produce a significant serological response until the piglets are about 12 weeks of age. Earlier vaccination of piglets from infected or vaccinated sows is ineffective because high levels of maternal antibodies interfere with a serological response stimulated by the vaccine.[114] Maternal immunity interferes with the development of active immunity from vaccination until at least 15 weeks of age, even when the colostral titers are low. Thus, in a situation in which the majority of sows have been infected or vaccinated, vaccination of weaned pigs may not yield desirable results. Both inactivated virus and attenuated live virus vaccines provide similar results when piglets born from vaccinated sows are vaccinated before colostral immunity has waned.

22.1.29.9.5.3

Growing and finishing pigs

The optimal vaccination strategy for growing and finishing pigs in an eradication program is controversial. In eight persistently infected herds vaccinations, both I/N and I/M[115] were made at 4 and 10 weeks of age.[116] Only one vaccination is given to

finishing pigs in endemic areas in Europe. However, this does not reduce the prevalence of infection in finishing pigs in herds with a high prevalence. Double vaccination of finishing pigs will reduce the spread of the virus, but extensive spread can still occur.[28] The presence of maternal antibodies may interfere with the induction of antibodies, and double vaccination 4 weeks later may boost immunity. Mean daily weight gain was also improved by a second vaccination with a direct economic benefit.

22.1.29.9.5.4

Marker or subunit vaccines

A major development in vaccination against pseudorabies has been the introduction of genetically engineered live vaccine strains used to make marker or subunit vaccines. Vaccination with modified live gene-deleted vaccines is now an integral part of pseudorabies eradication programs worldwide.[117] The most common gene deletions are for **glycoproteins E (gE)** or **gI** and **G (gG)** or **gX**, and **gIII**.[118] A gD/gE negative vaccine was described.[119] In Europe, use of **gE**-vaccines has become the standard. In the United States, a gG–gE – pseudorabies vaccine has been introduced.[63] These vaccines in conjunction with a **companion diagnostic test**, can **distinguish between naturally infected and vaccinated animals**. Colostrum can also be used to monitor antibodies against gI protein of the virus.[120]

A study comparing I/N and I/M vaccination showed that pigs given both vaccines (I/N and I/M) had a significantly better clinical and virological protection after challenge than the single I/N vaccination.[121] The recombinant vaccines are able to circumvent the inhibition of active immunity that occurs when maternally derived antibody is still present.[117,122] Animals vaccinated with a deleted vaccine are not able to mount an immune response against the protein whose gene has been deleted in the vaccine virus genome. In contrast, wildtype virus-infected animals produce antibodies against all the viral glycoproteins. Differentiating ELISAs, specific for the deleted marker protein, then allow discrimination between infected animals, which can be culled from the herd, and vaccinated animals. These vaccines reduce the severity of clinical disease and viral shedding. However, the presence of colostral antibodies in growing pigs may 1402
interfere with an immune response, which may result in increased virus excretion on challenge exposure. Repeated vaccination is needed to provide some protective immunity against challenge exposure to virulent virus. 1403

These mutants have also been rendered thymidine kinase-deficient (TK–) mutants, and are avirulent and immunogenic. Pigs inoculated with these mutants are resistant to experimental challenge with the virulent virus, and the virulent virus cannot be recovered from the ganglia, which suggests that vaccination reduced colonization of the ganglia. The ideal vaccine strain should prevent clinical disease and mortality, should not be transmitted to non-immunized animals, should prevent colonization of the ganglia by a potential superinfecting virulent virus and thereby reduce the natural reservoir of the virus. The TK – mutant virus possesses these desirable characteristics. The high efficacy of recently constructed gI-negative deletion mutant vaccines of pseudorabies virus provide a sound basis for implementing the 'gI' approach to the future control of the disease.

Piglets born from sows vaccinated with deleted (gIII-, TK) strains at 3 days and 9 and 11 weeks of age developed detectable antibodies that lasted up to 100 days of age when vaccinated.[123] Maternal antibodies in piglets from sows vaccinated with gIII-deleted vaccine decay to undetectable levels at 7 weeks of age. Vaccination of these piglets at 3 days of age with the same vaccine results in a priming effect, which protects the piglets against virulent virus challenge at 7 weeks of age.[124,125] Thus, effective protection could be provided by active immunization from birth through weaning, in the nursery and into the growing and finishing stages of production.

Although genetically engineered live virus vaccines have been shown to be efficacious and safe, there is a possibility of spread between vaccinated and unvaccinated animals, of persistence in the field and of recombination between different vaccine strains, which can lead to enhanced virulence. New viral mutants lacking glycoproteins gD, gE, gG, and gI may form the basis for the development of new vaccines that do not recombine.[126] A gB deletion vaccine has been described for I/N use and has been shown to produce both local and serum antibodies.[127] Recently, a DNA vaccine was shown to give as good a response as gD plasmid vaccine but the DNA vaccine had to be given intradermally.[128] It can overcome maternally derived antibody[129] and the vaccine described in this case still gave protection against infectious PRV challenge at the end of the finishing period.

Even more radical is a vaccine with a granulocyte-macrophage colony stimulating factor (GM-CSF) which has also been given in a DNWA formulation.[130]

Experimentally, immunized pigs can be latently infected with the wild-type virus without being detected by the gE-specific ELISA routinely used to discriminate between infected and vaccinated pigs.[124] Thus, gE seronegative pigs may still be infected and be a source of infection.

Remarkable progress has been made with the use of gI-deleted vaccines. Intensive regional vaccination of finishing pigs with a gI-deleted vaccine along with companion diagnostic tests, reduced the seroprevalence in infected finishing herds from 81% to 19% in 2 years.[131] Vaccination increases the virus dose needed for establishment of infection, and decreases the level and duration of virus excretion after infection. In the control group, with routine disease control, no significant change in seroprevalence occurred. The consistent application of intensive vaccination of all breeding herds in a region, including those herds participating in a production chain, can also decrease the prevalence of infection in heavily infected areas.[132] The intensive regional vaccination did not completely eliminate virus infections within these herds; the source of infection was not determined.[31] It is suggested that the virus either circulated at a low level within herds, or its introduction or reactivation did not lead to an extensive spread of the virus. A voluntary vaccination program on individual farms was unsuccessful in reducing the prevalence of virus-infected breeding pigs. The importation of breeding stock from outside the area is associated with a higher prevalence of virus-infected pigs because of lack of vaccination. The introduction of infections can be reduced by purchasing virus-free animals and by increasing farm biosecurity procedures.

Vaccination of breeding herds three times annually to insure a high level of immunization can lead to elimination of the disease when the reproduction ratio is less than 1.[133]

The method used for vaccination may influence the effect of the vaccine.[134] Using glycoprotein vaccines, IM vaccination in the neck, and six-point ID vaccination in the back provided the best protection; six-point ID injections resulted in a better vaccination than two-point injections. Body weight changes and viral excretion after challenge were compared with virus-neutralizing titers, antigen-specific IgG and IgA responses in serum, and virus-specific lymphoproliferative responses in peripheral blood during the immunization period.

An intensive eradication program in farrow–finish herds using a gI-deleted vaccine in breeding and growing – finishing pigs, and decreases of movement and mixing of growing–finishing pigs was successful in 3 years.[135] The initial goal was to decrease viral spread in the growing–finishing pigs, which enabled production of seronegative replacement gilts. Increases in the number of sows culled, combined with an increase in the number of seronegative replacement gilts, resulted in a decrease in seroprevalence of sows. Bimonthly serological monitoring indicated minimal spread of the virus in the growing–finishing pigs after 1 year. Beginning at 18 months after initiation of the program, test and removal of seropositive sows commenced in all herds. All herds were released from quarantine within 3 years, indicating that eradication can be achieved by vaccination and management changes designed to minimize the spread of virus combined with test-and-removal procedures.

An attenuated gI-deleted–TK-deleted vaccine was used to eradicate the virus from a large farrow–finish herd in Sweden.[136] At the start of the program, 86% of the breeding animals were seropositive. The breeding stock was vaccinated every 4 months and monitored serologically. Seropositive sows and boars were culled at an economic rate. The herd was declared gI-negative 39 months after the start of the program. Monitoring the herd for another 4 years, until all vaccinated animals had been culled, revealed the herd free of the virus.

In New Zealand, progress towards eradication using a subunit vaccine is reported.[137] Those farms that combined vaccination with good management techniques, intensive testing and culling eradicated the wild virus infection within 2 years; those that made little or no progress has less than satisfactory standards of hygiene and did not practise an intensive testing and culling program.

Vaccination of both breeding stock and growing pigs is recommended. A combined vaccination–eradication program for the disease would generally comprise four phases:

1. A systematic and intensive vaccination campaign
2. Screening of pigs for gI-antibodies
3. Economic culling of infected breeding pigs
4. Final ending of vaccination.

Piglets at 3 days of age can be vaccinated with one of these genetically engineered vaccines and be protected from experimental challenge at 5 weeks of age. 1403 1404

A recent study has shown that infection with PRRSv does not inhibit the development of a vaccine-induced protection against PRV.[138]

Vaccination of cattle with an inactivated vaccine is recommended where they are in close contact with swine and where a low level of exposure is likely.

22.1.30 # VIRAL ENCEPHALOMYELITIS OF PIGS (TESCHEN DISEASE, TALFAN DISEASE IN THE UK, BENIGN ENZOOTIC PARESIS IN DENMARK, POLIOMYELITIS SUUM, PORCINE ENTEROVIRAL ENCEPHALOMYELITIS)

22.1.30.1 ## Synopsis

22.1.30.1.1 ### Etiology

Porcine enteroviruses capable of causing encephalomyelitis. Teschen virus, Talfan virus, and others

22.1.30.1.2 ### Epidemiology

Certain European countries, Scandinavia, and North America. Morbidity 50%; case fatality 70–90%. Teschen in Europe. Talfan in UK. Viral encephalomyelitis in North America.

Transmitted by direct contact

22.1.30.1.3 ### Signs

Acute: Teschen. Fever, stiffness, unable to stand, tremors, convulsions, and death in few days

Subacute: Talfan. Milder than acute form. Most common in pigs under 2 weeks of age. Morbidity and case fatality rate 100%. Outbreaks. Hyperesthesia, tremors, knuckling of fetlocks, dog-sitting, convulsions, blindness, and death in a few days. Milder in older growing pigs and adults

22.1.30.1.4 ### Clinical pathology

Virus-neutralization tests

22.1.30.1.5 ### Lesions

Non-suppurative encephalomyelitis

22.1.30.1.6 ### Diagnostic confirmation

Demonstrate lesion and identify virus

22.1.30.1.7 ### Differential diagnosis list:

- Pseudorabies
- Hemagglutinating encephalomyelitis virus.

22.1.30.1.8 ### Treatment

None

22.1.30.1.9 ### Control

Outbreaks will cease and herd immunity develops

1404

1405

22.1.30.2 ## ETIOLOGY

A number of closely related, but antigenically different, enteroviruses, capable of growth in tissue culture, are causes of encephalomyelitis in pigs.[1] Porcine enteroviruses comprising at least 13 serotypes are grouped into three groups.[2,3] They can cause neurological disturbances, infertility and dermal lesions in pigs. **Teschen virus**, initially isolated in Czechoslovakia, is the most virulent and there have been a number of independent isolates, such as the Konratice and Reporyje strains.[4] **Talfan virus**, isolated from England, and other unnamed isolates appear less virulent. Teschen and Talfan virus

occur in subgroup 1, which is now called porcine enterovirus group 1 (PEV-1) but isolates from encephalomyelitis are also associated with other subgroups. In 2001 it was proposed that the teschoviruses be regrouped into three[5] with group 1 being the teschoviruses, group 2 the old PEV8 (V13 virus) and group 3 the old PEV9. In the system proposed[6] these are PEV-A and PEV-B. It is now proposed that the PEV-1 Talfan group be regarded as a new genus for the family Picornaviridae.[7] A recent study of group 2 suggests that it may have unique features and may be better called a new picornavirus genus.[8] Within subgroups, strains may be further differentiated using a complement fixation test and monospecific sera. There is variation in virulence between strains, and with many strains, clinical encephalitis following infection appears to be the exception rather than the rule.

22.1.30.3

EPIDEMIOLOGY

22.1.30.3.1

Occurrence and prevalence of infection

Prior to the early 1940s, the incidence of porcine viral encephalomyelitis was restricted to certain districts in Czechoslovakia. Since then, reports of the disease have come from many countries and there is serological evidence that the disease occurs throughout the world. The most severe form of the disease – Teschen disease – appears to be limited to Europe and Madagascar, but the milder forms – Talfan disease, poliomyelitis suum, and viral encephalomyelitis – occur extensively in Europe,[9] Scandinavia, and North America and recently in Japan.[10] A recent outbreak in Indiana has been described[8] and it was ascribed to porcine enterovirus serogroup 5 or 6 with the only characteristic feature being the histological lesions of polioencephalomyelitis. Losses due to the disease result primarily from deaths.

Serological surveys in areas where the disease occurs indicate that a high proportion of the pig population is infected without any clinical evidence of the disease. In the majority of field occurrences, porcine encephalomyelitis is a sporadic disease affecting either one or a few litters, or a small number of weaned pigs.

22.1.30.3.2

Morbidity and case fatality

The morbidity rate is usually about 50% and the case fatality rate 70–90% in Teschen disease as it is described in eastern Europe. The disease in Denmark and the United Kingdom is much milder, and the morbidity rate about 6%.

22.1.30.3.3 ## Methods of transmission

Infection is transmitted by ingestion and the aerosol routes. The virus replicates primarily in the intestinal tract but also in the respiratory tract. When infection first gains access to a herd the spread is rapid and all ages of pigs may excrete virus in feces.

22.1.30.3.4 ## Risk factors

22.1.30.3.4.1 ### Animal risk factors

Depending upon the virulence of the infecting strain, clinical disease primarily affects young pigs but may occur in older pigs at the same stage. As infection becomes endemic and herd immunity develops, excretion of the virus is largely restricted to weaned and early grower pigs. Adults generally have high levels of serum antibody, and suckling piglets are generally protected from infection by colostral and milk antibody. Sporadic disease in suckling pigs may occur in these circumstances in the litters of non-immune or low antibody sows, and may also occur in weaned pigs as they become susceptible to infection. In the recent outbreak in the USA the major factor was the rapid decline of the maternal antibody in the piglets (<21 days). Seroconversion then coincided with the increased mortality in the herd.

22.1.30.3.4.2 ### Pathogen risk factors

The causative viruses will infect only pigs and are not related to any of the viruses that cause encephalomyelitis in other species. They are resistant to environmental conditions, including drying, and are present principally in the central nervous system and intestine of affected pigs.

22.1.30.4 ## PATHOGENESIS

The virus multiplies in the intestinal and respiratory tracts and may invade to produce viremia. Invasion of the CNS may follow, depending upon the virulence of the strains and the age of the pig at the time of infection.[1] There is some strain difference in the areas of the CNS primarily affected, which accounts for variations in the clinical syndrome, and it is possible for histopathological evidence of encephalitis to be present in pigs that have shown no clinical signs of the disease. This may also occur with adenovirus infection.

22.1.30.5

CLINICAL FINDINGS

22.1.30.5.1

Acute viral encephalomyelitis (Teschen disease)

An incubation period of 10–12 days is followed by several days of fever (40–41°C, 104–106°F). Signs of encephalitis follow, although these are more extensive and acute after intracerebral inoculation. They include stiffness of the extremities, and inability to stand, with falling to one side followed by tremor, nystagmus, and violent clonic convulsions. Anorexia is usually complete, and vomiting has been observed. There may be partial or complete loss of voice due to laryngeal paralysis. Facial paralysis may also occur. Stiffness and opisthotonos are often persistent between convulsions, which are easily stimulated by noise and often accompanied by loud squealing. The convulsive period lasts for 24–36 hours. A sharp temperature fall may be followed by coma and death on the 3rd–4th day, but in cases of longer duration the convulsive stage may be followed by flaccid paralysis affecting particularly the hind limbs. In milder cases, early stiffness and weakness are followed by flaccid paralysis without the irritation phenomena of convulsions and tremor. In a recent case in the UK the pigs were off-color, showed anterior limb paralysis and were reluctant to rise and were therefore euthanased. Pigs were bright and keen to eat and drink.

22.1.30.5.2

Subacute viral encephalomyelitis (Talfan disease)

This is called Talfan disease in the United Kingdom, viral encephalomyelitis in North America and Australia, and poliomyelitis suum in Denmark. The subacute disease is milder than the acute form, and the morbidity and mortality rates are lower. The disease is most common and severe in pigs less than 2 weeks of age. Older sucking pigs are affected also, but less severely and many recover completely. Sows suckling affected litters may be mildly and transiently ill. The morbidity rate in very young litters is often 100% and nearly all the affected piglets die. In litters over 3 weeks old there may be only a small proportion of the pigs affected. The disease often strikes suddenly – all litters in a piggery being affected within a few days – but disappears quickly, subsequent litters being unaffected. Clinically, the syndrome includes anorexia, rapid loss of condition, constipation, frequent vomiting of minor degree, and a normal or slightly elevated temperature. In some outbreaks, diarrhea may precede the onset of nervous signs. 1405

Nervous signs appear several days after the illness commences. Piglets up to 2 weeks of age show hyperesthesia, muscle tremor, knuckling of the fetlocks, ataxia, walking 1406

backwards, a dog-sitting posture and terminally lateral recumbency, with paddling convulsions, nystagmus, blindness, and dyspnea. The Dresden type of Teschovirus caused an ataxia and recumbency in a large group of pigs about 5 days after removal of the sows and housing in the production unit.[11] Older pigs (4–6 weeks of age) show transient anorexia and posterior paresis, manifested by a swaying drunken gait, and usually recover completely and quickly. In the Japanese outbreak the pigs had at 40 days of age a flaccid paralysis of the hind limbs and became recumbent although they could move using their forelegs.[10] After the initial group of affected piglets the disease disappeared.

Individual instances or small outbreaks of 'leg weakness' with posterior paresis and paralysis in gilts and sows may also occur with this disease.

22.1.30.6 ## CLINICAL PATHOLOGY

22.1.30.6.1 ### Serology

Virus-neutralization and complement fixation are useful serological tests. Antibodies are detectable in the early stages and persist for a considerable time after recovery.

22.1.30.6.1.1 #### Detection of virus

Virus is present in the blood of affected pigs in the early stages of the disease, and in the feces in very small amounts in the incubation period before signs of illness appear, but brain tissue is usually used as a source of virus in transmission experiments. A nested – PCR has recently been described in which all 13 serotypes and field isolates were detected[2] using three sets of primer pairs. It is more rapid and less time-consuming as a test than tissue culture and serotyping.

22.1.30.7 ## NECROPSY FINDINGS

There are no gross lesions. Microscopically, there is a diffuse non-suppurative encephalomyelitis and ganglioneuritis with involvement of gray matter predominating. This takes the form of perivascular cuffing with mononuclear cells,[10] focal gliosis, neuronal necrosis and neuronophagia. The brain stem and spinal cord show the most extensive lesions, often with the most severe lesions in the cord. These take the form of degenerated or necrotic nerve cells in the ventral horns, glial nodules, occasional

hemorrhage, and a diffuse infiltration of mononuclear cells. In the white matter the changes were not so severe.[10] Infiltration of mononuclear cells was also seen in the dorsal root ganglia (together with degenerated ganglion cells and neuronophagia) spinal nerves and sciatic nerves. Swollen myelin sheaths and axonal spheroids were seen in the peripheral nerves. Meningitis, particularly over the cerebellum, is an early manifestation of the disease. No inclusion bodies are visible in neurons, in contrast to many cases of pseudorabies. Virus can be isolated from the brain and spinal cord early in the disease course, or from the blood during the incubation period. Recovery of the virus from the gastrointestinal tract does not confirm the diagnosis, as asymptomatic enteric infection is common. Isolation attempts may prove unrewarding, necessitating the correlation of clinical, serological and necropsy findings in order to confirm the diagnosis.[2] Recently, an experimental infection with PEV3 produced tremors and paralysis 3–7 days post-infection with all the animals having pericarditis and myocarditis.[12]

22.1.30.7.1

Samples for confirmation of diagnosis

- **Histology** – one-half of mid-sagittally-sectioned brain, spinal cord including spinal ganglia, gasserian ganglion (LM)
- **Virology** – one-half of mid-sagittally-sectioned brain, spinal cord (ISO, FAT). In the recent German cases[11] the virus was isolated from all the tissues examined but not from the blood. A technique using monoclonal antibodies has been described that can be used either as an immunofluorescent agent or for immuno-electron microscopy.[13] New techniques using the reverse transcription polymerase chain reaction (RT-PCR) have recently been described that allow the distinction of both Porcine Teschoviruses (group I) and viruses of PEV1 and 2.[14] In the recent Japanese description cytopathogenic agents were recovered from the tonsil, brainstem and cerebellar homogenates The PCR products from these were then sequenced and the isolate confirmed as PTV. Isolation of virus is not easy and needs to be from the brain and spinal cord. There are no firm indications of when to take material and a good consistent site in the brain for isolation as yet.[15]

22.1.30.7.1.1

DIFFERENTIAL DIAGNOSIS

The diagnosis of diseases causing signs of acute cerebral disease in pigs is difficult because of the difficulty in neurological examination of pigs, and the diagnosis usually depends on extensive diagnostic laboratory work.

Pseudorabies and hemagglutinating encephalomyelitis virus disease are similar clinical syndromes. In general, viral diseases, bacterial diseases, and intoxications must be considered as possible groups of causes; careful selection of material for laboratory examination is essential. The differentiation of the possible causes of diseases resembling viral encephalomyelitis is described under pseudorabies.

22.1.30.8

TREATMENT

There is no treatment.

22.1.30.9

CONTROL

The sporadic occurrence of the disease in a herd is usually an indication that infection is endemic. When outbreaks occur the possibility that introduction of a new strain has occurred should be considered. However, by the time clinical disease is evident it is likely that infection will be widespread and isolation of affected animals may be of little value. A closed herd policy will markedly reduce the risk of introduction of new strains into a herd, but there is evidence that they can gain access by indirect means. The sporadic nature of the occurrence of most incidents of porcine encephalomyelitis does not warrant a specific control program.

Teschen disease is a different problem. Vaccines prepared by formalin inactivation of infective spinal cord and adsorption onto aluminium hydroxide have been used extensively in Europe. Two or three injections are given at 10- to 14-day intervals and immunity persists for about 6 months. A modified live virus vaccine is also available.

In the event of its appearance in a previously free country, eradication of the disease by slaughter and quarantine should be attempted if practicable. Austria reported eradication of the disease which had been present in that country for many years. A slaughter policy was supplemented by ring vaccination around infected premises.

22.1.31

SPORADIC BOVINE ENCEPHALOMYELITIS (SBE, BUSS DISEASE, TRANSMISSIBLE SEROSITIS)

Sporadic bovine encephalomyelitis (SBE) is associated with a chlamydia, and characterized by inflammation of vascular endothelium and mesenchymal tissue. There is secondary involvement of the nervous system, with nervous signs, in some cases.

22.1.31.1

ETIOLOGY

The disease is associated with *Chlamydophila* (*Chlamydia*) *pecorum*.[1, 2] It resists freezing but is highly susceptible to sodium hydroxide, cresol, and quaternary ammonium compounds in standard concentrations. The chlamydia can be passaged in guinea-pigs and hamsters, and adapted to grow in the yolk sac of developing chick embryos.

22.1.31.2 EPIDEMIOLOGY

22.1.31.2.1 Occurrence

The disease has been reported only from the United States, Japan, and Israel but a provisional diagnosis has been made in Australia, where it is thought that the disease may have been present for some time, and in Canada, South Africa and Hungary. In the United States, it occurred most commonly in the midwestern and western States but there have been no reports of its occurrence for the last 30 years.

Sporadic cases or outbreaks occur in individual herds. Although the disease has not reached serious economic proportions in the endemic, there is some serological evidence that widespread subclinical infections occur.[1]

Only cattle and buffalo are affected, and calves less than 6 months of age are most susceptible. Other domestic and experimental species appear to be resistant. There is no seasonal incidence, cases appearing at any time of the year. A strong and apparently persistent immunity develops after an attack of the disease.

22.1.31.2.2 Prevalence of infection

22.1.31.2.2.1 Morbidity and case fatality rates

The occurrence is sporadic, but outbreaks have occurred resulting in severe loss due to both deaths of animals and loss of condition. Morbidity rates average 12.5% (5–50%), being highest in calves (25%) and lowest in animals over a year old (5%). Mortality rates average about 31% and are higher in adults than in calves. In affected herds a stage of herd immunity is reached when only introduced animals and newborn calves are susceptible.

22.1.31.2.3 Method of transmission

The method of spread is not known. Spread from farm to farm does not occur readily. On some farms only sporadic cases may occur, but on others one or two cases occur every year. In still other herds the disease occurs in outbreak form, with a number of animals becoming affected within a period of about 4 weeks. The epidemiology of SBE resembles in many ways that of bovine malignant catarrh (BMC). The organism can be

isolated from many organs, including liver, spleen and central nervous system, and from the blood, feces, urine, nasal discharges, and milk in the early stages of the disease. There is some evidence that the organism is eliminated in the feces for several weeks after infection.

22.1.31.3 PATHOGENESIS

The causative agent is not specifically neurotropic and attacks principally the mesenchymal tissues and the endothelial lining of the vascular system, with particular involvement of the serous membranes. Encephalomyelitis occurs secondarily to the vascular damage.

22.1.31.4 CLINICAL FINDINGS

Affected calves are depressed and inactive, but the appetite may be unaffected for several days. Nasal discharge and salivation with drooling are frequently observed. A fever is common (40.5–41.5°C, 105–107°F), and remains high for the course of the disease. Dyspnea, coughing, a mild catarrhal nasal discharge, and diarrhea may occur. During the ensuing 2 weeks, difficulty in walking and lack of desire to stand may appear. Stiffness with knuckling at the fetlocks is evident at first, followed by staggering, circling, and falling. Opisthotonos may occur but there is no excitement or head-pressing. The course of the disease varies between 3 days and 3 weeks. Animals that recover show marked loss of condition and are slow to regain the lost weight.

22.1.31.5 CLINICAL PATHOLOGY

22.1.31.5.1 Hematology

In experimental cases, leukopenia occurs in the acute clinical stage. There is a relative lymphocytosis and depression of polymorphonuclear cells.

22.1.31.5.2 Detection of agent

The causative agent can be isolated from the blood in the early clinical phase, and can be used for transmission experiments in calves and guinea pigs, and for culture in eggs. Elementary bodies are present in the guinea-pig tissues and yolk-sac preparations.

22.1.31.5.2.1

Serology

Serological methods, including a complement fixation test for the detection of circulating antibody, are available although there is difficulty in differentiating antibodies to the chlamydia from those to the typical psittacosis virus.

22.1.31.6

NECROPSY FINDINGS

A fibrinous peritonitis, pleurisy and pericarditis, accompanied by congestion and petechiation are characteristic. In the early stages, thin serous fluid is present in the cavities, but in the later stages this has progressed to a thin fibrinous net covering the affected organs, or even to flattened plaques or irregularly shaped masses of fibrin lying free in the cavity. Histologically, there is fibrinous serositis involving the serosa of the peritoneal, pleural, and pericardial cavities. A diffuse encephalomyelitis involving particularly the medulla and cerebellum, and a meningitis in the same area are also present. Minute elementary bodies are present in infected tissues and in very small numbers in exudate. The necropsy findings are diagnostic for SBE and confirmation can be obtained by the complement fixation test or serum neutralization tests.

22.1.31.6.1

DIFFERENTIAL DIAGNOSIS

Clinically, the disease resembles other encephalitides of cattle. The epidemiology and pathogenesis resembles bovine malignant catarrh (BMC), but the mortality rate is much lower, there are no ocular or mucosal lesions, and the serositis of SBE does not occur in bovine malignant catarrh. A viral encephalomyelitis of calves (Kunjin virus) has been identified, but has not been associated with clinical signs of disease of the nervous system. An encephalomyocarditis virus, a primary infection of rodents that also occurs in primates and causes myocarditis in pigs, has been transmitted experimentally to calves but without causing significant signs of disease.

Listeriosis is usually sporadic and is accompanied by more localizing signs, especially facial paralysis and circling.

Rabies may present a very similar clinical picture, but the initial febrile reaction and the characteristic necropsy findings as well as the epizootiological history of SBE should enable a diagnosis to be made.

Lead *poisoning* can be differentiated by the absence of fever, the more severe signs of motor irritation, and the shorter course of the disease. Because of the respiratory tract involvement, SBE may be easily confused with pneumonic pasteurellosis, especially if outbreaks occur, but in the latter disease nervous signs are unusual and the response to treatment is good.

1407

1408

22.1.31.7 TREATMENT

Broad-spectrum antimicrobials control the agent in vitro. However, clinical results with chlortetracycline and oxytetracycline have been irregular, but may be effective if used in the early stages of the disease.

22.1.31.8 CONTROL

Control measures are difficult to prescribe because of lack of knowledge of the method of transmission. It is advisable to isolate affected animals. No vaccine is available.

22.1.32 OVINE ENCEPHALOMYELITIS (LOUPING-ILL)

22.1.32.1 Synopsis

22.1.32.1.1 Etiology

Louping-ill virus, flavivirus

22.1.32.1.2 Epidemiology

Disease of sheep (and red grouse), and occasionally other domestic animals and man, transmitted by Ixodes ricinus. Occurs predominantly in lambs and yearling sheep in Great Britain and Europe in the spring, associated with tick rise

22.1.32.1.3 Clinical findings

Fever, neurological dysfunction, muscle tremor, incoordination, bounding gait. Recovery or convulsions and death

22.1.32.1.4 Lesions

Non-suppurative encephalitis

22.1.32.1.5 Diagnostic confirmation

Serology, demonstration of virus

22.1.32.1.6 Control

Vaccination, tick control

22.1.32.2 ETIOLOGY

Louping-ill virus belongs to the genus *Flavivirus*, which is divided into eight groups, one of which is the tick-borne encephalitis group. Louping-ill is antigenically related to the tick-borne encephalitis viruses most of which cause disease in man but not in sheep. Louping-ill virus occurs in Great Britain and Norway, but similar disease occurs elsewhere and there is antigenic diversity between isolates from different geographic areas. Viruses that are closely related to louping-ill virus, and that cause very similar disease but in different regions of the world, include **Russian spring-summer encephalitis virus, Turkish sheep encephalitis virus, Spanish sheep encephalitis virus** and **Greek goat encephalomyelitis**.[1–3] In sheep, concurrent infection with the agent of tick-borne fever *Ehrlichia (Cytoecetes) phagocytophila* enhances the pathogenicity of the virus.[4]

22.1.32.3 EPIDEMIOLOGY

22.1.32.3.1 Occurrence

22.1.32.3.1.1 Geographic occurrence

Louping-ill was originally considered to be restricted to the border counties of Scotland and England but is now recognized as also occurring in **upland grazing**

areas of Scotland, in Ireland, south west England, and in Norway; related viruses and disease occur in Spain, Bulgaria, and Turkey.[2,3,5] The distribution of the disease is regulated by the occurrence of the **vector tick** *Ixodes ricinus*, which requires suitable hosts and a ground layer microclimate of high humidity throughout the year. In these areas, louping-ill can be a common infection and may be a significant cause of loss.

22.1.32.3.1.2

Host occurrence

Louping-ill virus can infect and produce disease in a wide variety of vertebrates including man, but **predominantly sheep** are affected because of their susceptibility and the fact that they are the main domestic animal species that graze the tick-infested areas.

While sheep (and red grouse) are the only animals that commonly develop clinical disease, *Ixodes ricinus* feeds on a number of different hosts and the adult tick requires a large mammalian host. As a consequence, seropositivity and occasional clinical disease occur in all **other domestic species**, especially goat kids, but also cattle, horses,[6] pigs,[7] and humans.[8]

Traditionally, pigs have not been free-ranged on upland tick-infested areas,[7] but they are susceptible to experimental infection by all routes.

Red deer (*Cervus elaphus*) and roe deer (*Capreolus capreolus*) are hosts for the tick in Scotland,[9] and the elk (*Alces a. alces*) may be in Sweden. Infection in these species is usually sub-clinical; however, when these animals are subjected to the stress of captivity, clinical illness is more likely to occur. This may be important to commercial deer farmers.[10]

22.1.32.3.2

Transmission

22.1.32.3.2.1

Tick transmission

The reservoir for the disease and the major vector is the **three host tick** *I. ricinus*, which requires a single blood meal at each stage of development. The tick feeds for approximately 3 weeks every year and completes its life cycle in 3 years. The larval and nymphal stages will feed on any vertebrate but the **adult female** will engorge and mate only on larger mammals.[3,9] The tick becomes infected by feeding on a viremic host and the virus translocates to the salivary gland of the subsequent stage to provide

a source of infection at feeding in the following year. Transtadial transmission of the virus occurs, but transovarial transmission does not, and thus only the nymph and adult ticks are capable of transmitting the disease. The activity of the tick is **seasonal**. The tick is active at temperatures between 7 and 18°C, and most ticks feed in the spring with peak activity dependent upon the latitude and elevation of the pasture but generally occurring in April and May. In some areas there is a second period of activity of a separate population of *I. ricinus* in the autumn during August and September. While infected ticks can transmit the infection to a large number of vertebrate hosts, only sheep, red grouse (*Lagopus scoticus*), and possibly horses attain a viremia sufficient to infect other ticks and act as **maintenance hosts**.[3,4,9] Grouse amplify the virus, deer amplify the vector and hares (*Lepus timidus*) amplify both. Infection in red grouse is accompanied by a high mortality, and the louping-ill virus is essentially maintained in an area by a sheep–tick cycle and hare tick cycle.[9]

22.1.32.3.2.2

Non-tick transmission

Although the major method of spread is by the bites of infected ticks, spread by **droplet infection** is of importance in man, and the infection can be transmitted in animals by hypodermic needle contamination and other methods. The virus is not very resistant to environmental influences and is readily destroyed by disinfectants. Pigs fed the carcasses of sheep that had died of louping-ill become infected with the louping-ill virus. The virus is excreted in the **milk** of experimentally infected female goats, and infects sucking kids to produce an acute disease.[11] Virus is also excreted in the milk of ewes during the acute stages of infection but, paradoxically, does not result in the transmission of the infection to lambs. Grouse can be infected by eating infected ticks and this is considered a major mechanism of infection for grouse.[11]

22.1.32.3.3

Host and environmental risk factors

The epidemiology of disease is dictated by the biology of the tick, and disease is **seasonal** with occurrence during spring when the ticks are active. The prevalence of infection, as measured by seropositivity, is high in areas where the disease is enzootic. In these areas, the annual incidence of disease varies but there are cases every year and they occur predominantly in **yearlings and in lambs**. In enzootic areas, the majority of the adult sheep have been infected and are immune. Colostral immunity from these ewes will protect their lambs for approximately 3 months and these lambs are resistant to

infection during the spring rise of the ticks. Ewe lambs that are retained in the flock are susceptible to infection at the second exposure the following spring.

The proportion of infected animals that develop clinical disease in any year is estimated to vary from 5 to 60% and is influenced by the intensity of the tick vector, the immune status of the flock, the age at infection, nutritional status, and factors such as cold stress, herding and transport, and the occurrence of intercurrent disease.[3,4,9] **Naive animals** introduced to an enzootic area are at high risk for infection and clinical disease.

1408 1409

Intercurrent infection with *Ehlichia (Cytoecetes) phagocytophilia* and *Toxoplasma gondii* have been shown to increase the severity of experimental tick-borne fever in young lambs, but the relevance of this association to naturally occurring disease is uncertain. It would appear that concurrent infection with louping-ill and tick-borne fever is unlikely to occur in the field in young lambs because colostral immunity will protect against infection with the louping-ill virus, whereas colostral immunity is not protective against tick-borne fever. Similarly, the superinfection of *Rhizomucor pusillus* on this concurrent infection has been observed in experimental conditions, but is not a commonly recorded observation in natural disease.

22.1.32.3.4

Zoonotic implications

Louping-ill is a zoonosis.[8] The major risk for veterinarians is with the **postmortem** examination and handling of tissues from infected animals. Laboratory workers are also at risk. Shepherds and abattoir persons who handle infected sheep are also at risk. The occurrence of virus in the milk of goats and sheep is a risk for human disease where **raw milk** is consumed.

22.1.32.4

PATHOGENESIS

After tick-borne infection, the virus proliferates in the regional lymph node to produce a **viremia** which peaks at 2–4 days and declines with the development of circulating antibody prior to the development of clinical disease. Invasion of the central nervous system occurs in the early viremic stage in most if not all infected animals, but in most the resultant lesions are small and isolated and there is no clinical neurological disease.[12] The occurrence of clinical disease is associated with the replication of the virus in the brain, severe inflammation throughout the central nervous system, and necrosis of **brainstem** and **ventral horn neurons**. The reason for more severe disease in some animals appears to be related to the rapidity and extent of the immune response. Animals that survive exposure to

louping-ill virus have an earlier immune response to the infection and have high concentrations of antibody in the cerebrospinal fluid.

In experimental studies, there is a more severe and prolonged viremia and a higher mortality from louping-ill when there is concurrent infection with tick-borne fever. Sheep with tick-borne fever have severe neutropenia, lymphocytopenia, defective cellular and humoral immunological responses,[13] and the high mortality associated with concurrent infection with this agent is believed due to enhanced viral replication of the louping-ill virus.[3]

The dual infection in experimental sheep also facilitates fungal invasion and a systemic mycotic infection with *Rhizomucor pusillus*.[4]

22.1.32.5

CLINICAL FINDINGS

In most **sheep**, infection is inapparent. There is an incubation period of 2–4 days followed by a sudden onset of high fever (up to 41.5°C, 107°F) for 2–3 days followed by a return to normal. In animals that develop **neurological disease** there is a second febrile phase during which nervous signs appear. Affected animals stand apart, often with the head held high and with twitching of the lips and nostrils. There is marked tremor of muscle groups and rigidity of the musculature, particularly in the neck and limbs. This is manifested by jerky, stiff movements and a **bounding gait**, which gives rise to the name ‘louping-ill’. Incoordination is most marked in the hindlimbs. The sheep walks into objects and may stand with the head pressed against them. Hypersensitivity to noise and touch may be apparent. Some animals will recover over the following days, although there may be residual torticollis and posterior paresis. In others, the increased muscle tone is succeeded by recumbency, convulsions and paralysis, and death occurs as early as 1–2 days later. Young lambs may die suddenly with no specific nervous signs.

The clinical picture in **cattle** is very similar to that observed in sheep, with hyperesthesia, blinking of the eyelids and rolling of the eyes, although convulsions are more likely to occur in cattle, and in the occasional animals that recover from the encephalitis there is usually persistence of signs of impairment of the central nervous system.

Horses also show a similar clinical picture to sheep, with some showing a rapidly progressing nervous disease with a course of approximately 2 days and others a transient disorder of locomotion with recovery in 10–12 days.

The infection is usually subclinical in adult **goats** but the virus is excreted in the milk and kids may develop severe acute infections. In **humans** an influenza-like disease followed by meningoencephalitis occurs after an incubation period of 6–18 days. While recovery is common, the disease can be fatal and residual nervous deficiencies can occur.[8]

22.1.32.6

CLINICAL PATHOLOGY

The initial viremia that occurs with infection declines with the emergence of serum antibody and virus is no longer present in the blood at the onset of clinical signs. Hemagglutination inhibition, complement-fixing and neutralizing antibodies can be detected in the serum of recovered animals. Hemagglutination inhibition and complement-fixing antibodies are relatively transient, but neutralizing antibodies persist. **Hemagglutination inhibition** IgM antibody develops early in the disease and can be used as an aid to diagnosis in animals with clinical disease.[3] Analysis of CSF is usually not considered because of the zoonotic risk.

22.1.32.7

NECROPSY FINDINGS

No gross changes are observed. Histologically, there are perivascular accumulations of cells in the meninges, brain and spinal cord, with neuronal damage most evident in cerebellar Purkinje cells and, to a lesser extent, in the cerebral cortex. Louping-ill virus can be demonstrated in formalin-fixed tissues by the **avidin–biotin–complex immunoperoxidase** technique.[14]

22.1.32.7.1

Samples for confirmation of diagnosis

- **Virology** – chilled brain, halved mid-sagitally (VI)
- **Histology** – fixed brain, other half (LM, IHC).

22.1.32.7.1.1

DIFFERENTIAL DIAGNOSIS

The disease is restricted to areas where the vector tick occurs and this allows or denies a possible diagnosis.

- In lambs, the disease has clinical similarities with delayed swayback, spinal abscess, and some cases of tick pyemia. Spinal abscess occurs shortly following a management procedure such as docking or castration or with tick pyemia; it

has a longer clinical course, is commonly present at C7–T2, and can be established by radiographic examination. Tick pyemia can also occur in flocks that have louping-ill and the determination of the contribution of each disease to flock mortality relies on clinical, epidemiological, and postmortem examination

- In yearlings, the disease has similarities to spinal ataxia due to trauma, to gid (*Coenuris cerebralis*), and to the early stages of polioencephalomalacia
- In adults, the disease in sheep bears resemblance to some stages of scrapi, tetanus, hypocalcemia, hypomagnesemia, pregnancy toxemia, and ovine kangaroo gaite.

1409

1410

22.1.32.8

TREATMENT

An antiserum has been used and affords protection if given within 48 hours of exposure, but is of no value once the febrile reaction has begun. It is not available commercially. Animals with clinical disease should be sedated if necessary during the acute course of the disease, and should be kept in a secluded and dark area with general supportive care.

22.1.32.9

CONTROL

The prevention of louping-ill requires either the prevention of exposure of sheep to tick-infested pastures or the immunization of animals prior to exposure. **Immunization** has been the traditional approach.

Historically, a formalinized tissue vaccine derived from brain, spinal cord, and spleen was used, and provided excellent immunity in enzootic areas. The vaccine was not without risk for persons manufacturing it and at one stage led to an outbreak of scrapie where the vaccine was prepared from sheep incubating the disease. Currently, vaccination is with a formalin-killed tissue culture derived vaccine where the virus has been concentrated ten-fold by methanol precipitation or ultrafiltration.[15] The vaccine is administered in an oil adjuvant. A single dose of this vaccine will give protection for at least 1 year and possibly up to 3 years, and has been shown to give excellent results in field trials. The vaccine is used in the autumn, or in the early spring 1 month before the anticipated tick rise, in all ewe lambs that will be held for flock replacements. Vaccination of pregnant ewes twice in late pregnancy is recommended to insure adequate passive immunity to the lambs via the

colostrums.[15] A recombinant vaccine has also been shown to offer protection against infection.[16]

The limited geographical occurrence of this disease and commercial economics has, and may, restrict the availability of vaccines. Consequently **tick control**, or the elimination of infection from pastures, may be the required approach in the future. The intensity of tick infestation of pastures can be reduced by influencing the microclimate that they require for survival. In some areas this can be achieved by ditching and drainage of the pastures. The control of the causative tick using acaricides is detailed in the section on ticks and provides some protection against disease.

Epidemiological, modeling, and experimental studies indicate that sheep and red grouse and hares are the only maintenance hosts for the virus[9,11] and this, coupled with the fact that there is no transovarial transmission of the virus in the tick, offers a potential method for eradication of the infection from an area. This approach, the elimination of grouse and hares, would be radical and would require an economic assessment of its benefit–cost in relation to alternate methods of control.

22.1.33 # CAPRINE ARTHRITIS ENCEPHALITIS (CAE)

22.1.33.1 ## Synopsis

22.1.33.1.1 ### Etiology

Retrovirus

22.1.33.1.2 ### Epidemiology

Persistent infection with perinatal and horizontal spread. Management of herd influences extent of seropositivity

22.1.33.1.3 ### Clinical findings

This disease of goats is characterized by arthritis, especially of the carpal joints (big knee), in mature goats, and acute leukoencephalomyelitis in young goats. Indurative mastitis, and less commonly chronic pneumonia and chronic encephalomyelitis, occur in older goats

22.1.33.1.4 Clinical pathology

Increased mononuclear cell count in CSF. Lower or inverted CD4:CD8 ratio in peripheral blood

22.1.33.1.5 Lesions

Chronic polysynovitis, degenerative joint disease in adults. Non-suppurative demyelinating encephalomyelitis. Interstitial pneumonia

22.1.33.1.6 Diagnostic confirmation

Microscopic lesions and agar gel immunodiffusion test (AGID)

22.1.33.1.7 Treatment

None

22.1.33.1.8 Control

Segregation of the newborn from seropositive animals, and feeding of virus-free colostrum and milk. Prevention of horizontal transmission. Regular testing with segregation or culling

22.1.33.2 ETIOLOGY

Caprine arthritis encephalitis (CAE) viruses are non-oncogenic retroviruses belonging to the subfamily Lentvirinae. The causal viruses are not identical but are of a single virus type, and genetically distinct isolates may have different virulence. Antigenic drift is common and may facilitate the persistence of the virus in the host and the development of disease. There is a high degree of relatedness with the lentivirus associated with maedi-visna and ovine progressive pneumonia in sheep; the ovine and caprine lentiviruses share nucleotide homology and serological properties,[1] and there is a similarity in the disease pathogenesis.

22.1.33.3 ## EPIDEMIOLOGY

22.1.33.3.1 ### Geographic occurrence

There is serological evidence of infection in most areas of the world, including Europe, the United Kingdom, North America, Africa, Arabia, Australia, New Zealand, and South America.[2] While there is sampling bias, one global study indicates that there are marked differences in prevalence between countries and that the prevalence is noticeably less in developing countries that have not had importations of dairy-type goats from North America or Europe. Other countries, such as New Zealand, have a low prevalence with a distribution related to exotic importations.[3]

There may also be variation in seroprevalence within countries. In the United States, the prevalence of infection in goats in the western and middle parts of the country is approximately 50% of all goats tested, which is about twice that in the eastern and Rocky Mountain areas.[3,4] Herd seroprevalence is greater than 60% in all regions. The seroprevalence within herds shows clustering, with most herds falling into either high or low seroprevalence groups. There are area differences in age prevalence of seropositivity, with some surveys showing no difference and others showing an increasing prevalence with increasing age.[3,5,6]

Clinical disease is much less common than infection and the annual incidence of disease in heavily infected flocks is usually low and approximates 10%.

22.1.33.3.2 ### Host risk factors

22.1.33.3.2.1 #### Breeds

All breeds are susceptible to infection but several studies have recorded apparent differences in breed susceptibility, which may reflect differences in management practices such as feeding practices of colostrum and milk, or genetic differences in susceptibility.[2,4,6,7] There is a higher prevalence of seropositive goats in family-owned farms as compared to institutional herds, which might reflect a greater movement of goats among the former.[3]

22.1.33.3.2.2

Age

There is no age difference in susceptibility to experimental infection. Some herds show similar seroprevalance across age groups, while others show an increasing seroprevalence with increasing age. These differences probably reflect differences in management between herds and differences in the relative importance of the mechanisms of transmission between herds. Increasing prevalence with age reflects management systems that increase the risk of acquiring infection from horizontal transmission. Leukoencephalomyelitis occurs predominantly in young kids and arthritis in older goats.

22.1.33.3.3

Method of transmission

Greater than 75% of kids born to infected dams may acquire infection, and infection can potentially be transmitted to them by several routes. Infection can also occur in older goats by different routes.

22.1.33.3.3.1

Colostrum and milk

Observation of the natural disease and experimental studies indicate that the **primary mode** of transmission is through the colostrum and milk. The presence of antibody in colostrum does not prevent infection. The virus can be isolated both from the cells in the milk and from cell-free milk from infected dams; kids born of non-infected dams but fed colostrum and/or milk from infected dams become infected.[7] A single feeding of infected milk can be sufficient to infect a kid.[8] Conversely, the risk of infection is much lower in kids that are removed from the doe immediately after birth and reared on pasteurized milk, and some can be reared free from infection.[9]

22.1.33.3.3.2

Other perinatal transmission

It is probable that intrauterine infection can occur, but this appears to be of infrequent occurrence and not of significance to the control of the disease.[4,7] The disease can be transmitted by contact both during and following the perinatal period, and perinatal transmission is important in the epidemiology of the disease. Perinatal transmission could result from contact with vaginal secretions, blood, saliva or respiratory secretions but the relative importance of these is not known.

22.1.33.3.3.3

Contact transmission

Horizontal transmission occurs at all ages and older goats can be infected by oral challenge with virus.[10] Contact transmission will result in the spread of the disease when an infected animal is introduced into an infection-free herd and has been one cause of spread in countries where the infection has been introduced with imported animals.

Prolonged **co-mingling** of uninfected with infected animals is likely to promote horizontal transmission.

22.1.33.3.3.4

Other routes

Milk contains free virus and virus-infected cells and shared **milking** facilities increase the risk of cross-infection. Possibly this results from the transfer of infected cells in milk during the milking process. **Iatrogenic** and **venereal** transmission are possible but appear of limited significance.[7]

22.1.33.3.4

Experimental reproduction

Arthritis and mastitis have been reproduced by oral, intravenous and intra-articular challenge with virus; however, pneumonia is not a feature of the experimental disease. **Leukoencephalomyelitis** in young lambs can be reproduced by intracerebral challenge but this form of the disease has not been reproduced by more natural challenge routes. Strains of the virus can be **neuroadapted** by passage and show increased neurovirulence but not neuroinvasiveness, suggesting that these are separate characteristics.[10,11]

The relatedness of the caprine and the ovine lentiviruses is evident with experimental infections. Experimentally, infection with the caprine virus has been transferred to lambs by feeding them infected colostrum or by injection. Experimental infection of lambs is followed by viremia and seroconversion, but some strains of the virus produce no clinical or histopathological evidence of disease. Kids have been similarly infected with the maedi virus. The arthritic form of the disease has been produced experimentally in Cesarean-derived kids injected with virus isolated from the joints of infected goats. Despite these experimental cross-species transmissions, there is no evidence for cross-species transmission in the field.[7]

22.1.33.3.5

Economic importance

There is a high prevalence of infection in many countries, and several of these have opted for national or breed-associated control programs. There is a higher **cull rate** in infected herds, as high as 5–10% of goats are culled each year for arthritis, and affected animals cannot be entered for show. Seropositive herds have a higher incidence of disease.[12]

There are conflicting reports on the effect of infection on **productivity** in goat herds,[12–15] but seropositive goats are reported to have significantly lower milk production, a reduced length of lactation, lower 300-day yields of milk, and impaired reproductive performance.[13,14]

22.1.33.4

PATHOGENESIS

Animals infected at birth remain persistently infected for life, although only a proportion develop clinical disease. The virus persistently infects a proportion of cells of the monocyte–macrophage type, and the expression and shedding of virus occurs as infected monocytes mature to macrophages.[16,17] Disease is the result of inflammation resulting from the reaction of the host immune system to expressed virus. The development of neutralizing antibody does not arrest viral replication because of the continual expression of antigenic variants of the virus with differing type-specific neutralization epitopes.[18,19] However, the immune complexes are believed to be the basis for the chronic inflammatory changes in tissues.[20] Goats that are vaccinated with the virus develop more severe clinical disease following challenge than non-vaccinated controls. The lesions are **lymphoproliferative** in nature and the virus causes a multisystem disease syndrome, which primarily involves synovial-lined connective tissue causing chronic arthritis, the udder causing swelling and hardening of the glands, with or without mastitis, and the lungs causing a chronic interstitial pneumonia.

A retrovirus infection, detected by electron microscopy and the presence of reverse transcriptase activity is suspected as the cause of an immunodeficiency syndrome in llamas characterized by failure to thrive, anemia, leukopenia, and recurrent infection.[21]

22.1.33.5 CLINICAL FINDINGS

22.1.33.5.1 Joints

Arthritis occurs predominantly in adult goats and is a chronic hyperplastic synovitis, which is usually noticeable only in the **carpal joints**, giving rise to the lay term of **big knee**. Tarsal joints may also be clinically affected. The onset may be insidious or sudden, and unilateral or bilateral. If the goat is lame in the leg, lameness is not severe. Affected goats may live a normal life span but some lose weight gradually, develop poor hair coats, and eventually remain recumbent most of the time with the consequent development of decubitus ulcers. Dilatation of the atlantal and supraspinous bursae occurs in some cases. The course of the disease is long, lasting several months. The arthritis may be accompanied by enlargement and hardening of the udder and by interstitial pneumonia, although this may be clinically inapparent. There can be **herd and area differences** in the clinical expression of the disease, and in some outbreaks in Australia pneumonia has been a prominent feature.

Radiographically, there are soft tissue swellings in the early stages, and calcification of periarticular tissues and osteophyte production in the later stages. Quantitative joint scintigraphy provides an accurate non-invasive method for assessing the severity of the arthritis in a live animal.[22]

1411

1412

22.1.33.5.2 Brain

Leukoencephalitis occurs primarily in kids from 1 to 5 months of age. The syndrome is characterized by unilateral or bilateral posterior paresis and ataxia. In the early stages, the gait is short and choppy, followed by weakness and eventually recumbency. In animals that are still able to stand, there may be a marked lack of proprioception in one hindlimb. Brain involvement is manifested by head tilt, torticollis and circling. Affected kids are bright and alert, and drink normally. Kids with unilateral posterior paresis usually progress to bilateral posterior paresis in 5–10 days. The paresis usually extends to involve the forelimbs so that tetraparesis follows. Most kids are euthanized. The interstitial pneumonia that commonly accompanies the nervous form of the disease is usually not sufficiently severe to be obvious clinically.

22.1.33.5.3

Udder

Indurative mastitis, or **hard bag**, is often initially detected a few days after kidding. The udder is firm and hard but no milk can be expressed. There is no systemic illness and no bacterial mastitis. Recovery is never complete but there may be some gradual improvement.

22.1.33.6

CLINICAL PATHOLOGY

The **synovial fluid** from affected joints is usually brown to red-tinged, and the cell count is increased up to 20000 μL with 90% mononuclear cells. The cerebrospinal fluid may contain an increased mononuclear cell count. There is a reduction in monocytes in peripheral blood, a decrease in the number of $CD4^+$ lymphocytes, and a lower or inverted CD4:CD8 ratio.[23]

22.1.33.6.1

Serological testing

For the live animal there are a number of test systems available whose sensitivity and specificity varies.[24] **Agar gel immunodiffusion test** (**AGID**) is widely used for detection of infection. Seropositive animals are considered to be infected with the virus, maternal antibody is lost by approximately 3 months of age, a seropositive test in a goat older than 6 months of age is considered evidence of infection and most, but not all, animals have a persistent antibody response and remain seropositive for life.

A negative test does not rule out the possibility of infection. There may be a considerable delay between infection and the production of test reactive antibody. It is possible that in some infected goats there is insufficient virus expression to lead to an antibody response.[10,25]

A competitive-inhibition ELISA that detects antibody to the surface envelop of the virus has very high sensitivity and specificity and may aid considerably in the determination of the infection status for animal movement.[29] Tests with possibly greater sensitivity and/or specificity are described,[24] but are not generally available.

Identification of the presence of CAE is usually provided by isolation of the virus from tissue explants into tissue culture.[1] PCR techniques can be used to detect the presence of antigen.[26,30]

22.1.33.7

NECROPSY FINDINGS

At necropsy of a case of the **arthritic form** there is emaciation and chronic polysynovitis. Typically, degenerative joint disease affects most of the joints of animals submitted for necropsy. Periarticular tissues are thickened and firm and there is hyperplasia of the synovium. The local lymph nodes are grossly enlarged and a diffuse **interstitial pneumonia** is usually present. Mammary glands are frequently involved although gross changes are restricted to induration and increased texture. Microscopically, lymphoplasmacytic infiltrates of the interstitial tissues of mammary gland, lung and synovium are characteristic. In the **neural form** the diagnostic lesions are in the nervous system and involve the white matter, especially of the cervical spinal cord and sometimes the cerebellum and the brain stem. The lesion is a bilateral, **non-suppurative demyelinating encephalomyelitis**. The infiltrating mononuclear leukocytes tend to be more numerous in the periventricular and subpial areas. There is usually also a mild, diffuse, interstitial pneumonia in this form of the disease. In some cases, a severe lymphoplasmacytic interstitial pneumonia with extensive hyperplasia of type II pneumocytes can occur in the absence of neurologic disease.

Culture of the virus is difficult but can be attempted. A variety of nucleic acid recognition tests, including in situ hybridization and PCR have been developed.[30] An immunohistochemical technique for detection of the virus has also been reported.[27] For most cases, confirmation of the diagnosis is based on the characteristic microscopic lesions, preferably supported by antemortem serologic results.

22.1.33.7.1

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed lung, bronchial lymph node, mammary gland, synovial membranes, one-half of midsagittally-sectioned brain, spinal cord (LM, IHC)
- **Serology** – heart blood (ELISA, AGID)
- **Virology** – lung, synovial membrane, mammary gland, hindbrain (PCR, VI).

22.1.33.7.1.1

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the arthritic form of the disease includes the other infectious arthritides, such as those associated with mycoplasma and chlamydia.

Leukoencephalitis must be differentiated from:

- Swayback due to copper deficiency
- Spinal abscess
- Cerebrospinal nematodiasis
- Listeriosis
- Polioencephalomalacia.

22.1.33.8 TREATMENT

There is no treatment likely to be of value for any form of the disease.

22.1.33.9 CONTROL

A measure of control can be achieved by testing the herd every 6 months, and segregating or culling of seropositive animals. More complete control is dependent on preventing/ minimizing perinatal transmission of infection to the kid, particularly colostrum and milk transmission, coupled with identifying infected animals and maintaining them physically separated from the non-infected animals or culling them from the herd.

22.1.33.9.1 Prevention of perinatal transmission

Early recommendations for control concentrated on control of milk transmission but it is now recognized that this must be coupled with segregation. Newborn kids should be removed from the dam immediately at birth. There should be **no contact with the dam**, and fetal fluids and debris should be rinsed off the coat. **Heat-treated** goat colostrum or cow colostrum should be fed, followed by pasteurized milk or a commercial milk replacer. The kid should be segregated from the doe and other infected animals. There is a significant difference in subsequent seroconversions in herds that feed pasteurized colostrum and milk between those that segregate the kids at birth and for rearing and those that do not.[7]

22.1.33.9.1.1

Test and segregate/cull

Animals over 3 months of age should be **tested by AGID** every 6 months, and seropositive animals should be segregated or culled from the herd. The interval between infection and seroconversion varies between goats, and the optimal interval for testing has not been determined. More frequent testing may be required for large herds with high seroprevalence.[7] Segregation of seropositive and seronegative goats is essential, as horizontal spread in adult goats is important in maintaining and increasing infection rates in some herds and even a brief contact time can allow transmission.[28] Seropositive goats should be **milked** after seronegative goats where culling is not practised. The use of common equipment should be avoided.

1412

1413

Several countries have programs for **herd accreditation** of freedom from infection. The stringency of these schemes varies and they may be governmental or breed society accreditation programs. In general, they require that all adults in the herd test negative on two herd tests at a 6-month interval. There are also restrictions on the movement and purchase of animals, and periodic serological surveillance.

22.1.34 ## VISNA

22.1.34.1 ### Synopsis

22.1.34.1.1 #### Etiology

Neurovirulent strains of maedi-visna virus, a lentivirus

22.1.34.1.2 #### Epidemiology

Occurs in association with maedi but endemic visna only recorded in Iceland

22.1.34.1.3 #### Clinical findings

Afebrile disease with insidious onset. Progressive ataxia and wasting, long clinical course

22.1.34.1.4 #### Clinical pathology

Pleocytosis and elevated protein, virus, virus proteins, and antivirus antibody in cerebrospinal fluid

22.1.34.1.5 #### Lesions

Chronic demyelinating encephalomyelitis

22.1.34.1.6 #### Diagnostic confirmation

Histology, demonstration of virus

22.1.34.1.7 #### Treatment

None

22.1.34.1.8

Control

As for ovine progressive pneumonia

22.1.34.2

ETIOLOGY

Visna is associated with an ovine lentivirus and is the neurological manifestation of maedi-visna disease. Ovine lentivirus consists of a variety of strains that vary in their ability to infect target cells and cause disease. There are neurovirulent and non-neurovirulent strains,[1] and neurovirulence can be enhanced by intracerebral passage of virus.[2] Visna usually occurs in conjunction with maedi lesions in the lungs, and 10–18% of sheep with maedi have histological lesions of visna in the brain.[3,4]

22.1.34.3

EPIDEMIOLOGY

22.1.34.3.1

Occurrence

Visna is a disease of sheep and rarely of goats. Visna was originally recorded in Iceland and was a significant cause of death in the epizootic of maedi-visna that occurred in that country. It always occurred in association with maedi and was generally of sporadic occurrence and lesser importance than the pulmonary manifestation of the infection although in some flocks it was the major manifestation of the complex.[4] Visna has not been seen in Iceland since 1951 and maedi-visna has since been eradicated from Iceland.

Despite the widespread occurrence of maedi-visna or ovine progressive pneumonia in many countries visna is a very **uncommon disease** and a significant occurrence of clinical disease has seldom been recorded in countries other than Iceland.[4–8] The reason for this is not known but might be due to an increased susceptibility of the Icelandic breed of sheep to the neurological form of the disease, or to differences in maedi-visna virus strain neuroinvasiveness and neurovirulence. Maedi-visna virus was first reported in Britain in the late 1970 and the clinical expression since that time had largely been maedi occasionally with coexistent visna. However, recently there has been the occurrence of visna with no evidence of respiratory disease suggesting that a neurotropic strain might be emerging in that country.[9]

22.1.34.3.2

Experimental transmission

Experimental transmission of the infection and the disease is effected by intracerebral inoculation and spread occurs from these to commingled sheep.[10] The **incubation period** and the course of the disease are very long; clinical signs may not appear for 2 years after experimental inoculation.

22.1.34.4

PATHOGENESIS

The virus infects cells of the monocyte – macrophage lineage and replicates its RNA genome via a DNA intermediate provirus which is integrated into the chromosomal DNA of the host cell. Replication is limited and does not proceed beyond the synthesis of provirus in most cells. Persistent production of viral antigen results in lymphocytic hyperplasia. Although age has little effect on the development of disease, fetal and neonatal lambs have slightly greater permissiveness for replication of the virus. However, free infectious virus is present only in small quantities, but over very long periods. The genotype of the host is important and all breeds of sheep do not react to the same degree. Thus, Icelandic sheep react much more severely than English breeds.

There are two basic lesions, an inflammatory lesion which is not related to the occurrence of nervous signs, and a focal demyelination in the brain and spinal cord, the occurrence of which is related to the appearance of paresis.[11] Experimental immunosuppression greatly reduces the severity of lesions, by suppressing the cellular proliferative response without suppressing the growth of the virus and post-infection immunization enhances the severity of experimental visna.[12] Viral nucleic acid and proteins are present in oligodendrocytes, and demyelination is believed to result from the direct effect of the virus on these cells as well as being the result of an inflammatory response provoked by the presence of these antigens.[13]

1413

1414

22.1.34.5

CLINICAL FINDINGS

The disease has an **insidious onset** and the early clinical signs include lagging behind the flock because of **ataxia and body wasting**. The body wasting and the hindlimb ataxia are progressive. Affected animals show hypermetria and may stumble or fall as they traverse uneven ground or when making sudden turns. There is no fever, and a normal appetite and consciousness are retained. Additional signs include severe tremor of the facial muscles,

and knuckling of the distal limbs so that the animal stands on the flexed tarsi. Some animals may show a head tilt. Aimless wandering and blindness occur in some sheep.[7]

The clinical picture is not unlike that of scrapie without the pruritus. During the course of the disease, periods of relative normality may occur. Affected animals may show clinical signs for several months before final paralysis necessitates slaughter. The disease is **always fatal**. The clinical syndrome in goats is the same as that for sheep.

22.1.34.6

CLINICAL PATHOLOGY

There is an increased number of mononuclear cells in the cerebrospinal fluid, an elevated protein, and positive Pandy test.[4,8] The **pleocytosis** is variable during the course of the disease.[4] Virus, virus antigen, and antibody are also demonstrable in cerebrospinal fluid.[3] Serological tests are detailed under the section on ovine progressive pneumonia.

22.1.34.7

NECROPSY FINDINGS

Muscle wasting and an interstitial pneumonia may be visible but there are no gross changes in the central nervous system. The characteristic histological lesion is patchy, demyelinating encephalomyelitis. The inflammatory infiltrate is predominantly comprised of lymphocytes and macrophages. Demyelination occurs in the white matter of the cerebrum and cerebellum, and in the spinal cord. The histological character of the lung is typical of ovine lentivirus-associated pneumonia. Isolation of the virus is difficult. Typical neural lesions and a positive serological titer usually suffice for confirmation of the diagnosis. Immunohistochemical tests and PCR-based assays have been successfully employed to confirm this lentiviral infection in lung, mammary gland,[14] and even third eyelid[15] but the use of these tests to confirm of the infection in CNS tissues is not well documented.

22.1.34.7.1

Samples for confirmation of diagnosis

- **Histology** – fixed spinal cord, one-half of midsagittally-sectioned brain, lung, mammary gland, joint synovium (IHC, LM)
- **Serology** – heart blood serum (AGID, ELISA)
- **Virology** – chilled brain, spinal cord, lung, mammary gland (PCR, ISO).

22.1.34.7.1.1

DIFFERENTIAL DIAGNOSIS

Visna is a sporadic disease of mature sheep with an insidious onset of muscle wasting, progressive ataxia and having a long clinical course. These characteristics differentiate it from other diseases of sheep manifest with ataxia. Differentials include:

- Scrapie
- Delayed organophosphate toxicity
- Cerebrospinal nematodiasis
- Segmental axonopathy (Murrurrundi disease).

22.1.34.8

TREATMENT AND CONTROL

There is no treatment. Visna is a rare disease. Iceland achieved control by slaughter eradication; other control procedures are those for ovine progressive pneumonia.

22.1.35 # BORDER DISEASE (HAIRY SHAKER DISEASE OF LAMBS, HAIRY SHAKERS, HYPOMYELINOGENESIS CONGENITA)

22.1.35.1 ## Synopsis

22.1.35.1.1 ### Etiology

Pestivirus strains in the border disease and bovine virus diarrhea genotypes

22.1.35.1.2 ### Epidemiology

Congenital disease transmitted by persistently infected sheep, rarely cattle

22.1.35.1.3 ### Clinical findings

Abortions, stillbirths, barren ewes and the birth of small weak lambs some of which have an abnormally hairy birthcoat, gross tremor of skeletal muscles, inferior growth and a variable degree of skeletal deformity

22.1.35.1.4 ### Clinical pathology

None specific

22.1.35.1.5 ### Lesions

Hypomyelination in brain and spinal cord of lamb

22.1.35.1.6 ### Diagnostic confirmation

Detection of virus and/or demonstration of serological response

22.1.35.1.7 ### Treatment

Supportive

22.1.35.1.8

Control

Avoid infection of pregnant sheep. Identify and cull persistently infected animals

22.1.35.2

ETIOLOGY

The causal agent, border disease virus (BDV), is a **pestivirus** in the family Flaviviridae. **Four different species or genotypes** have been identified in the pestivirus genus; bovine virus diarrhea virus (BVDV) types 1 and 2, classical swine fever virus (CSFV) and border disease virus (BDV). Isolates from border disease predominantly fall within the BDV genotype but sheep and goat isolates also fall in the BVDV genotypes.[1,2] It is proposed that the BDV genotype can be divided into BDV-1, BDV-2, BDV-3 based on host origin and genetic and antigenic characteristics.[3]

Strains of BDV have differing pathogenicity, and variations in pathogenicity also result from interactions between the virus and different host genotypes, specifically between different breeds of sheep.[1–4] Persistent infections in sheep are associated with non-cytopathic strains of virus. An isolate of BDV is thought to have caused a leukopenic enterocolitis in sheep and growing lambs in the Aveyron region of France (**Aveyron disease**). The disease caused high mortality in sheep in this region in 1984 but has not occurred subsequently.[2]

22.1.35.3

EPIDEMIOLOGY

22.1.35.3.1

Occurrence

Border disease was originally described in the border country between England and Wales. It has subsequently been reported from most of the major sheep-producing countries[2,4–6] and probably occurs in all. The disease occurs naturally primarily in sheep and occasionally in goats. The prevalence of infection is much higher than the incidence of clinical disease as the latter only occurs when there is infection during pregnancy.

Studies on **seroprevalence** vary in design but suggest that pestivirus infections in sheep and goats are less common than in cattle and that there are considerable differences in seroprevalence between different geographical areas and flocks. Flock seroprevalence in different regions or countries generally falls within the range of 5 to 50%. The prevalence of seropositive females within positive flocks is influenced by age with a

lower seroprevalence in sheep 4 to 8 months of age than in older sheep. Seroprevalence is higher in flocks with persistently infected sheep but there can still be a significant proportion of seronegative sheep present in a flock containing persistently infected sheep.[7]

1414
1415

22.1.35.3.2

Source of infection

Infection can be introduced into a flock with the purchase of **persistently infected** replacement sheep. Persistently infected sheep excrete virus in nasal secretions, saliva, urine and feces,[2,6] and provide the major source of infection. A proportion of persistently infected sheep may survive to adulthood and may breed successfully to produce further persistently infected sheep.[8] However, the breeding efficiency of persistently infected sheep is poor and the probability of establishing lines of persistently infected sheep appears less than with the equivalent infection in cattle.[8,9]

Virus is also present in the **placenta and fetal fluids** at the birth of persistently infected lambs, and in the products of abortions resulting from infection with the virus in early pregnancy. In flocks where there is a long lambing period it is possible that this could provide a source for clinical disease in late lambing ewes. field observations suggest that transmission during the lambing period is limited.

Calves persistently infected with BVDV can infect sheep,[10] and in countries where pregnant sheep and cattle are housed in close proximity during the winter this can be an important source of infection for outbreaks of border disease. In some countries it appears the major source and recent studies in both Northern Ireland and the Republic of Ireland suggest that cattle are the primary source of infection for sheep in those countries.[11,12] In contrast BDV is the predominant ovine pestivirus in Great Britain and New Zealand.[13]

There is also evidence that bovine strains are important in goat infections.[1,14]

Free-living deer are also a potential source of infection. Outbreaks of disease are also recorded as the result of vaccinating pregnant goats with a pestivirus contaminated Orf vaccine.[15]

22.1.35.3.3

Transmission

Transmission is by sheep-to-sheep contact and experimental transmission has been effected with both oral and conjunctival challenge.[2,6]

The speed of spread of infection in a susceptible flock will vary with the management, and will be facilitated by factors such as close contact at mating time or gathering for any purpose. There is an increased risk for explosive outbreaks of border disease where animals are housed in early pregnancy.

22.1.35.3.4

Host risk factors

Border disease may occur as an outbreak or as a sporadic disease. When infection is introduced into a susceptible flock in early pregnancy, an outbreak with infertility, abortion and congenital disease in lambs from all ages of ewes is likely. Subsequently, older sheep in the flock will have immunity and disease is only common in introduced sheep and maiden ewes. Persistently infected ewes have reduced fertility but will give birth to congenitally affected lambs throughout their breeding life.[8,9] The disproportional occurrence of outbreaks of clinical disease in certain breeds suggests that these breeds have higher rates of persistently infected individuals.

22.1.35.3.5

Experimental reproduction

Border disease is readily reproduced by the experimental infection of pregnant ewes prior to 80 days' gestation and can be effected by oral, conjunctival and parenteral challenge.[6,9] Experimental disease can be produced with **both BDV and BVDV** strains.

The following have been produced experimentally, although there are strain differences in clinical and pathological manifestations:

- Placentitis
- Abortions
- Mummified fetuses
- Congenital malformations, including hydrocephalus, porencephaly, cerebellar hypoplasia and dysplasia, and arthrogryposis

- Fetal growth retardation
- Hypomyelinogenesis
- Birth of weak lambs with nervous disorders
- A hairy birthcoat.

Experimental infections of pregnant cows with BDV results in similar defects with placentitis, mummification and abortion of fetuses, intrauterine growth retardation with abnormal osteogenesis, and hypomyelinogenesis.

The disease has also been produced experimentally in goat kids by inoculation of pregnant goats but there are no abnormalities of hair coat, and embryonic mortality and abortion are more common than in the experimental disease in ewes.[16]

22.1.35.3.6 Economic importance

The effect of infection varies with the immune status of the flock and whether infection occurs during pregnancy. In fully susceptible flocks, abortion and neonatal lamb loss resulting from infection can be 25–75% of the expected lamb crop depending upon the strain of the virus.[9] An assessment of the economic losses due to infertility, abortion, neonatal losses, and low carcass weight indicate that an outbreak of border disease can result in a potential reduction of income in excess of 20%.[17]

22.1.35.4 PATHOGENESIS

22.1.35.4.1 Non-pregnant sheep

In adolescent and adult non-pregnant sheep, infection and viremia are **subclinical**. The IM inoculation of immunocompetent lambs with BDV results in a mild transient disease and a subsequent reduction in growth rate, but no gross or microscopic lesions.

22.1.35.4.2 Pregnant sheep

When BDV infects susceptible pregnant ewes the virus infects the placenta to produce an **acute necrotizing placentitis** and it subsequently invades the fetus. This may result in early embryonic death, abortion and stillbirth, the birth of lambs with malformations and/or neurological abnormalities, the birth of small weak lambs which are

immunosuppressed, or the birth of lambs with no clinical abnormality. The ultimate **outcome** of the infection depends on the age of the fetus, the properties of the strain of the virus, the dose of the virus, the genotype of the host, and the ability of the fetus to respond to the virus. **Fetal age** at the time if infection is most important, as it is the determinant of the ability of the fetus to mount an immune response to the infection.[2,6,9,18] Immune competence to the virus in sheep develops between approximately 61 and 80 days of gestation.

22.1.35.4.2.1

Infection in early pregnancy

Fetal death occurs when there is infection of the fetus with virulent strains prior to the development of immune competence and uncontrolled viral replication. Prenatal death is more likely to follow infections in early pregnancy but is recorded with infections from 45 to 72 days of gestation.

Persistent infections occur in lambs that survive infection in early pregnancy prior to the development of immune competence and result from maternal infections between 21 and 72 days of gestation but never later.[19] The virus is present in all organs, and lambs born persistently infected will remain so for their lifetime, with few exceptions; persistent infections have been recorded to at least 5 years of age.[9]

Most persistently infected sheep are unable to produce specific antibody to BDV but some show intermittent seropositivity with low antibody levels or occasionally undergo frank seroconversion.[19] The humoral response to other pathogens and antigens is normal. However, cell-mediated immunity is compromised, with change in T-cell populations and a deficiency in lymphocyte function.[20] Persistently infected lambs are more susceptible to intercurrent disease and commonly die before reaching maturity.

1415

1416

Hypomyelinogenesis occurs in persistently infected lambs and resolves spontaneously in lambs that survive to the age of 6 months.[21] Most of these lambs exhibit neurological dysfunction at birth, varying from a continuous light tremor to tonic–clonic contraction of the skeletal muscles involving the whole body and head (**shakers**).

Thyroid. A deficiency of the thyroid T_3 and T_4 hormones has been detected in lambs affected with border disease and may be the basic cause of the amyelination. The

enzyme 2,3-cyclic nucleotide- 3-phosphodiesterase is associated with normal myelination and depends upon normal amounts of thyroid hormone.[20] The deficiency in thyroid hormones may also result in the reduced rate of weight gain that occurs in infected lambs. Other studies suggest a direct infection of oligodendroglia with the virus as the cause of the defective myelination.[22,23]

Fleece abnormality also occurs in persistently infected lambs and results from an enlargement of the primary hair follicles and a concurrent reduction in the number of secondary follicles. The resulting hairiness is due to the presence of large medullated primary fibers. BDV appears to have no effect on the skin and birthcoat of coarse-fleeced breeds of sheep or on goats.

Intrauterine growth retardation is a common feature of infection with BDV and is initiated shortly after infection.[23] Deformities of the skeleton include abnormally shortened long bones, a reduction in crown–rump length and the long axis of the skull, which results in lambs appearing more compact and short-legged than normal (**goat lambs**). In the long bones there is evidence of growth arrest lines and disturbed osteogenesis and ossification.

Some persistently infected lambs have neither nervous signs nor abnormalities of the fleece and are phenotypically normal. This limits the value of identification of infected lambs based on the presence of clinical abnormality at birth.

22.1.35.4.2.2

In mid-pregnancy

When fetal infection occurs during the period of development of the ability to mount an immune response (between approximately 61 and 80 days of gestation) the effect is variable. Some fetuses infected at this stage respond with a severe inflammatory process in the CNS with nodular periarteritis, necrosis, and inflammation of the germinal layers of the brain. Resultant lesions are hydranencephaly, cerebellar dysplasia and multifocal retinal atrophy; such lambs exhibit behavioral abnormalities and more severe neurological disease than shaker lambs.[9,19,21]

22.1.35.4.2.3

Infection in late pregnancy

Infection of the fetus after 80 days of gestation is likely to be controlled or eliminated by a fetal immunological response. Such lambs are born without clinical disease and are virus-negative but have precolostral circulating antibody.

22.1.35.4.2.4

Goats

In goats, fetal death is the major outcome of infection of the pregnant doe with both BDV and BVDV, and infections prior to 60 days' gestation almost invariably result in reproductive failure.[16] Persistently infected shaker kids and clinically normal kids are born with infections around 60 days' of gestation but are a less common manifestation of the disease than occurs in sheep. The caprine fetus develops immune competence against pestiviruses between 80 and 100 days' gestation.[21]

22.1.35.4.3

Enteric disease

Experimental inoculation of a homologous strain of the BDV into persistently infected, but clinically recovered lambs results in a severe clinical syndrome characterized by persistent diarrhea and respiratory distress associated with an inflammatory lymphoproliferative response in the central nervous system, intestines, lungs, heart, and kidney. A similar syndrome is seen at weaning in some persistently infected sheep that survive early life.[2,9] This syndrome resembles certain aspects of mucosal disease in cattle, in which it is postulated that superinfection of persistently viremic immunotolerant cattle with a homologous strain of BVDV results in fatal mucosal disease. In such animals a specific and dynamic equilibrium exists between an attenuated form of the virus and the immunotolerant host. Disturbance of this equilibrium either by injection of the homologous strain of BDV, or some other factor, results in fatal disease.[9]

22.1.35.5

CLINICAL FINDINGS

The most obvious and characteristic features of border disease are evident at birth and relate to conformation and growth, fleece type, and neurological dysfunction.

22.1.35.5.1

Conformation

Affected lambs may have a lower birth weight than uninfected lambs, a decreased crown–rump length, and a shorter tibia/radius length so that they have a boxy appearance. The head has a shortened longitudinal axis and the cranium may be slightly domed (**goat lambs**).

22.1.35.5.2

Fleece

The fleece, when dry, appears **hairy** and rough due to long hairs rising above the fleece to form a halo, especially over the nape, back, flanks and rump.[24] This feature is most evident in medium- and fine-wool breeds and is not observed in the coarse kempy-fleeced breeds, such as the Scottish Blackface. The halo kemp fibers are shed with time and are most evident in the first 3 weeks of life. Some lambs have abnormal pigmentation occurring as patches of pigmented fleece or hair, or a totally pigmented fleece. This can occur in white-faced sheep.

22.1.35.5.3

Neurological dysfunction

Neurological dysfunction is manifest, with rhythmic tremors of the muscles of the pelvis and upper parts of the hindlimbs, or of the whole body, resulting in a characteristic jerking movement, and of the head and neck with rhythmic bobbing of the head (**shaker lambs**). In some less severe cases, only fine tremors of the ears and tail are evident. Tremors are most apparent during movement, and are absent while the lamb is sleeping. The tremors usually decline in severity as the lamb matures and may seem to disappear unless the animal is stressed. More severely affected lambs have difficult in rising, and if able to stand with assistance exhibit an erratic gait especially of the hindquarters. Paralysis does not occur. Affected lambs are often unable to nurse the ewe because they cannot hold onto the teat. Affected lambs appear languid and lie around listlessly. They do not suck as they should and bloat continuously, and the ewes' udders become engorged with milk.

Behavioral and visual defects with circling, head-pressing, nystagmus, and gross incoordination are seen in lambs with the type of infection producing hydranencephaly and cerebellar dysplasia. These lambs are of lighter birth weight but have normal birthcoats.

22.1.35.5.4

Growth rate

Growth rate is reduced, affected lambs are unthrifty, and the majority will die before or at weaning time from parasitism, pneumonia, a mucosal disease-like syndrome, or nephritis.[9,20] With good nursing care they can be reared but deaths may occur at any age. Puberty may be delayed and, in males, the testes are flabby and may not develop normally.

22.1.35.5.5

Reproductive performance

Impaired reproductive performance of the flock occurs from low fertility, abortion, and poor viability of lambs. Abortions usually are not noticed until lambing when it is evidenced by an unexpected increase in barren ewes. In goats, where there is often closer observation, the aborted fetuses may be reasonably well-developed, small and underdeveloped, or autolyzed and unrecognizable as a fetus in expelled fetal fluid.[16]

1416

1417

22.1.35.6

CLINICAL PATHOLOGY

There are no consistent changes in hematology or blood chemistry. Persistently infected lambs have changes in lymphocyte subpopulations, with a reduction in T-lymphocytes and an altered CD8:CD4 ratio.[6]

Virus can be detected by virus isolation, by antigen ELISAs, by PCR techniques and antibody by antibody ELISAs, or by serum neutralization tests.[2,25] A combination of serology and virus isolation can aid in the diagnosis of border disease.

22.1.35.6.1

Detection of persistently infected sheep

For diagnosis of border disease in newborn lambs, precolostral blood samples should be taken from both clinically normal and affected lambs. Persistently infected sheep are seronegative and BDV can be isolated from leukocytes in the blood buffy coat. Lambs infected late in gestation will be seropositive but virus-negative. Persistently infected lambs that have received colostrum from their dam will be seropositive until they lose the maternal passive immunity.

Persistently infected adolescent and adult sheep in a flock can be identified by the detection of virus in blood; however, this is expensive in large flocks and an alternative is test all sheep for antibody and then culture the buffy coat of seronegative sheep. Antigenic differences between laboratory strains and field virus can result in false-negative serologies and serological studies are best done with the homologous virus.[4,26]

22.1.35.6.2

Abortion

Serological tests are of limited value as an aid to the diagnosis of abortion associated with BDV infection. The infection of the ewe that results in abortion occurs several

weeks before clinical disease is apparent, and unless prospective samples can be taken there is little chance of a rise in antibody titers in paired samples. Seropositivity in ewes indicates that the flock has been exposed to pestivirus but does not incriminate it in a disease process. Seronegativity indicates that BDV is not the cause of the abortion, with the exception that aborting ewes, who themselves are persistently infected, will have no antibody titer.

22.1.35.7

NECROPSY FINDINGS

Gross findings may be normal, or may include an abnormal wool coat and a reduction in the size of the brain and spinal cord. Arthrogryposis, hydranencephaly, porencephaly, and cerebellar dysplasia may also be present. Histologically, there is a deficiency of stainable central myelin, with neurochemical and histochemical evidence of demyelination or myelin dysmorphogenesis. In most sheep the myelin defect resolves substantially during the first few months of life. The brain, which has been very small, returns to normal weight, and chemical composition and degree of myelination. The histological lesions of the skin consist of primary follicle enlargement, increased primary fiber size, and an increased number of medullated primary fibers.

Virus can be demonstrated by immunofluorescent staining of cryostat sections of tissues from affected lambs or by immunohistochemical staining of formalin-fixed material. Preferred tissues for such tests include brain, thyroid gland, and skin. Virus titers reach high levels in the placentomes, so caruncles or cotyledons should be cultured for virus. Isolates are non-cytopathic and the presence of viral antigens must be demonstrated by direct or indirect immunofluorescence or immune peroxidase techniques.

Owing to the closely related character of this pestivirus and BVDV, diagnostic tests to confirm infection parallel those for BVDV. Fetal serology can be useful to confirm exposure in abortions and stillbirths. PCR and ELISA techniques may be substituted for virus isolation if available.

22.1.35.7.1

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed skin, spinal cord, one-half of midsagittally sectioned brain, skin, thyroid, distal ileum, colon, cecum, thymus, spleen, liver, heart, kidney (LM, IHC)
- **Serology** – heart blood serum/thoracic fluid (VN)

- **Virology –** placenta/caruncle, thymus, lymph node, spleen, thyroid, brain, ileum (ISO, FAT, ELISA, PCR).

22.1.35.7.1.1

DIFFERENTIAL DIAGNOSIS

Congenital disease:

- Swayback (copper deficiency)
- Caprine encephalomyelitis.

Abortion:

- Enzootic abortion
- Listeriosis
- Toxoplasmosis
- Leptospirosis
- Rift Valley fever
- Akabane disease.

22.1.35.8

TREATMENT

There is no specific treatment. With care and nursing, many affected lambs will survive the immediate neonatal period but they grow poorly, are very susceptible to intercurrent disease during the growing period, and it is generally not economic to attempt to raise these lambs.

22.1.35.9

CONTROL

The principles are to attempt to engender a flock immunity and to avoid exposing sheep to infection in early pregnancy. Persistently infected sheep are a continuous source of infection and those that survive to breeding age can perpetuate the disease. They should be identified and culled.

The problem is with their identification, as some persistently infected lambs show no clinical or phenotypic abnormality. Lambs that are clinically affected at birth should be

permanently identified since the tremor and fleece abnormality disappear at 1–2 months of age and the lambs may no longer be recognizable as infected. Persistently infected animals can be identified by serological screening of the ewe lambs intended for replacement stock at 6 months of age (after maternal passive immunity has waned), followed by virus isolation in seronegative animals, but this is expensive and only practical in small flocks. An alternative is to keep no replacement ewes from an affected lamb crop.

Persistently infected sheep can be run with the flock when it is not pregnant, particularly with the replacement ewes, in an attempt to produce infection and immunity prior to pregnancy. They should be removed prior to breeding. While this can result in 'natural vaccination' the rates of infection and seroconversion in replacement females can be low.[7] In theory, cattle BVDV vaccines could be used to produce immunity but their efficacy would depend upon a significant relatedness to the BDV under consideration.

In most flocks a serious outbreak of the disease is followed by minor disease in subsequent years, the flock developing immunity in the initial outbreak.

In flocks that are free of infection, replacement ewes and rams should be screened for infection prior to purchase, or quarantined after arrival on the farm. Newly introduced sheep should be kept separate from the main flock until after lambing. Ideally, cattle should not be pastured or housed with pregnant sheep.

22.2 Viral diseases characterized by skin lesions

22.2.1 CONTAGIOUS ECTHYMA (CONTAGIOUS PUSTULAR DERMATITIS, ORF, SCABBY MOUTH, SOREMOUTH)

22.2.1.1 Synopsis

22.2.1.1.1 Etiology

Orf virus. Genus *Parapoxvirus*. Family Poxiviridae

22.2.1.1.2 Epidemiology

Primarily young lambs and kids. Morbidity may reach 100% and case fatality rate 5–15%. Rapid spread in flock by contact or via inanimate objects such as feed troughs, ear tag equipment and emasculators. Scabs from lesions remain infective in the environment for a long time. Orf can cause considerable set back when young lambs are affected and also has economic importance due to restriction of movement and trade of affected sheep. May infect humans

22.2.1.1.3 Signs

Papules, pustules, scabs covering ulceration, granulation, proliferation and inflammation. Lesions begin at oral mucocutaneous junction, oral commissures and spread to muzzle, oral cavity. Lambs cannot suck or graze. Malignant form occurs with invasion of alimentary tract. Severe systemic reaction can occur and lesions on coronets, ears, anus, and vulva. Lesions can be multifocal in goats

22.2.1.1.4 Clinical pathology

Electron microscopy. PCR

22.2.1.1.5 Lesions

Scabs, pustules, granulation tissue and secondary lesions. Eosinophilic cytoplasmic inclusion bodies

22.2.1.1.6

Diagnostic confirmation

Clinical recognition and identify virus by PCR

22.2.1.1.7

Differential diagnosis list:

- Ulcerative dermatosis
- Proliferative dermatitis (strawberry foot rot)
- Blue tongue
- Foot and mouth disease
- Sheep pox.

22.2.1.1.8

Treatment

Nothing specific; general care of lesions

22.2.1.1.9

Control

Isolation of affected animals. Vaccination

22.2.1.2

ETIOLOGY

Orf is associated with the orf virus, a type species of the genus *Parapoxvirus* (family Poxviridae). In addition to the orf virus (parapox ovis) the genus includes the viruses of bovine papular stomatitis (parapox bovis 1) pseudocowpox (parapoxvirus bovis 2) and a parapox virus of deer.[1–3] The orf virus withstands drying and is capable of surviving at room temperature for at least 15 years. Restriction endonuclease digests of DNA shows considerable heterogeneity between different field isolates.

22.2.1.3

EPIDEMIOLOGY

22.2.1.3.1

Occurrence

The disease occurs in sheep and goats and causes unthriftiness, varying degrees of pain, and some economic loss. It occurs most commonly in lambs 3–6 months of age when at pasture, although lambs 10–12 days of age and adult animals can be severely affected,

and outbreaks involving the lips and face of young lambs and the udders of the ewes also are common. Outbreaks occur at any time but they are most common in dry conditions when the sheep are at pasture, or in penned sheep being fed from feed troughs. The disease has occurred in musk ox in which it causes heavy losses, reindeer, mountain goats and bighorn sheep, chamois, caribou, Dall sheep, buffalo, wild goats, and camels. The virus can be passaged in rabbits if large doses are placed on scarified skin or injected ID. Mild lesions develop on the chorioallantois of the 9 to 12-day chick embryo. Guinea-pigs and mice are not susceptible.

The disease also occurs in humans working among infected sheep. In abattoir workers it is commonest in those handling wool and skins.[4]

22.2.1.3.2

Morbidity and case fatality

Outbreaks may occur in sheep and goats, with morbidity rates approaching 100% and case fatality rates from 5 to 15%.[5,6] The deaths that occur are due to the extension of lesions in the respiratory tract, but the case fatality rate may reach 15% if severely affected lambs are not provided with adequate care and support, or if secondary infection and cutaneous myiasis are allowed to occur. In the rare outbreaks where systemic invasion occurs, the case fatality rate averages 25% and may be as high as 75%. Under field conditions recovered animals are immune for 2–3 years, but no antibodies appear to be passed in the colostrum, and newborn lambs of immune ewes are susceptible.[5]

22.2.1.3.3

Methods of transmission

Scabs that fall off from healing lesions contain virus and remain highly infective for long periods in dry conditions, but survival of the disease in a flock may be the result of chronic lesions that exist for long periods on individual animals.[7] Infection can be from environmental persistence of the virus or from infected sheep. Spread in a flock is very rapid and occurs by contact with other affected animals or by contact with contaminated inanimate objects, such as feed troughs, ear-tagging pliers.[8] An outbreak of lesions on the tails is recorded in association with the use of docking instruments.[9]

It has been assumed that natural infections on pasture are the result of invasion of the virus after skin damage induced by prickly plants or stubble; application of a viral suspension to scarified skin is the established method of inducing orf.[10] However, an outbreak has occurred in a large group of lambs collected from several farms and

transported in a vehicle over a period of 23 hours.[11] There was no evidence of injury to their mouths.

22.2.1.3.4

Experimental reproduction

The disease is readily reproduced by introduction of virus onto scarified areas of skin. Immunity to re-infection is relatively solid at the site of initial infection but shorter duration lesions can be reproduced by re-challenge of these sheep at other sites.[10,12]

22.2.1.3.5

Risk factors

The primary risk factors are the presence of the virus and the immune status of the sheep.

A simulated shipping exercise has examined these risks.[13] Initially, the prevalence of scabby mouth on participating sheep farms was determined. The proportion of farms with evidence of the disease in weaner sheep was 23.6%, and on those farms with the disease the overall prevalence was 6.1%. Sheep from different farms are mixed, held at high stocking densities for approximately 3 weeks, and offered pelleted feed that can abrade the lips and mouth to promote development of the lesions. The major risk factor for the prevalence of the disease in sheep arriving in a feedlot after transportation from the farm was immunity to the disease. The arrival and mixing in the feedlot was also important for transmission of the infection to occur. Sheep vaccinated on the farm before road transportation to the feedlot had a lower prevalence at the end of the simulated shipping exercise.[13]

1418 1419

Inter-current infections may exacerbate the occurrence disease on rare occasions.

The disease has spread from clinically normal ewes to susceptible 2–4 years of age which were persistently infected with border disease virus[14] and lambs experimentally infected with *Ehrlichia phagocytophilia* and subsequently challenged with orf virus developed more severe lesions with a longer course than those in control lambs.[15]

22.2.1.3.6

Economic importance

The disease produces a minor set back except when it affects young sucking lambs with associated lesions on the teats and udders of their ewes. Loss from lamb mortality and secondary mastitis in these circumstances can be significant.

The disease assumed economic importance for Australia when shipments of sheep exported from Australia in 1989–1990 were rejected at some ports in the Middle East because of the disease[13] and this problem continues. Litigation is a concern when zoonotic infections occur at petting zoos or fairs.

22.2.1.3.7

Zoonotic implications

Orf virus is readily transmitted to humans. In the agricultural environment typical lesions occur at the site of infection, usually an abrasion infected while handling diseased sheep for shearing, crutching or drenching or by accidental means when vaccinating. Lesions progress from macular to papular stages, are usually single and localized on the hands, arm or face. The lesions are self limiting and heal without scaring after 6 to 7 weeks. They are pruritic and respond poorly to local treatment. Orf is also a zoonotic consideration in ‘petting zoos’ and fairs where children allow lambs to suck their fingers or otherwise become infected from handling sheep exhibits. Historically, orf has been a risk for industrial workers handling raw wool.

22.2.1.4

PATHOGENESIS

Damage to the skin is essential for the establishment of orf infection and the development of typical lesions.[10] Following viral challenge of mildly abraded skin, the virus does not establish in the damaged epidermis, but replicates in the cells of an underlying replacement epidermal layer derived from the walls of the wool follicles. Following scarification of ovine skin and topical application of the orf virus, antigen cannot be detected in the skin during the period when the epidermis is being renewed.[16] Virus can first be detected in the center of the newly differentiated epidermis immediately below the stratum corneum, 72 hours after infection. The location of the virus during the eclipse stage is unknown. The infection spreads laterally and uniformly from the new epidermis, initially in the outer stratum spinosum and subsequently throughout the entire depth of the epidermis. The skin reaction consists of a cellular response with necrosis and sloughing of the affected epidermis and underlying stratum papillare of the dermis. The cutaneous response to infection includes a delayed-type hypersensitivity reaction and an influx of inflammatory cells involving neutrophils, basophils, and possibly mast cells.[17] Class II dendritic cells are also involved and appear to form the basis of a highly integrated local dermal defense mechanism.[18] The lesions evolve through the stages of macule, papule, vesicle, pustule, scab formation, and resolution. The pustules develop within a few days, and rupture

resulting in ulcers and subsequently a thick overlying crust or scab forms which is shed within 3–4 weeks leaving no scar.[10] Immunity is solid but will last only about 8 months. While there is an antibody immune response to the virus[19] recovery is the result of cell-mediated immune mechanisms.[12] Experimentally, a secondary infection, following recovery from a primary infection, is milder and accelerated.[20] During the secondary challenge, pustules and scabs develop earlier, the lesions resolve more rapidly, and no vesicular stage may occur.[17]

22.2.1.5 CLINICAL FINDINGS

22.2.1.5.1 Sheep

Lesions develop initially as papules and then pustules, stages which are not usually initially observed, and progress to raised **moderately proliferative** area of granulation, and inflammation covered with a thick, tenacious scab. Time progression from the initial lesions to the formation of scabs is approximately 6 to 7 days. New lesions will develop during the first 10 days of infection. The first lesions develop at the **oral mucocutaneous junction**, usually at the oral commissures and are accompanied by swelling of the lips. From here they spread on to the muzzle and nostrils, the surrounding haired skin and, to a lesser extent, on to the buccal mucosa. They may appear as discrete, thick scabs 0.5 cm in diameter, or coalesce and be packed close together as a continuous plaque. fissuring occurs and the scabs are sore to the touch. They crumble easily but are difficult to remove from the underlying granulation. Affected lambs suffer a severe setback because of restricted sucking and grazing. In benign cases the scabs dry and fall off, and recovery is complete in about 3 weeks. Affected lambs sucking ewes may cause spread of the disease to the udder where a similar lesion progression is seen. Lesions on the **teats** predispose to mastitis and secondary infection of the skin lesions by bacteria or fly larvae occurs in some cases. In rams, lesions on the **scrotum** may be accompanied by fluid accumulation in the scrotal sac and associated temporary infertility. A high incidence of infection can also occur where the dominant lesions are on the feet, occurring around the coronary band, the dew claws and on the volar areas of the intervening skin.

Rarely, systemic invasion occurs and lesions appear on the coronets and ears, around the anus and vulva or prepuce, and on the nasal and buccal mucosae. There is a severe systemic reaction, and extension down the alimentary tract may lead to a severe

gastroenteritis, and extension down the trachea may be followed by bronchopneumonia. Lesions may also occur in the **mouth** involving the tongue, gums, dental pad or a combination of those sites.[21] These are more commonly seen in outbreaks affecting lambs less than 2 months of age. In the mucosa of the mouth these lesions do not scab but are papular erosive and surrounded by an elevated zone of hyperemia. Extensive painful and proliferative lesions occur on the gingival margins of the incisor teeth.

In some outbreaks the lesions on the skin are highly proliferative and present as raw raised granulating lesions without an overlying scab. This manifestation appears more common in Suffolk sheep and lesions are present on the lips, bridge of the nose and around the eyes. Cases of this proliferative form involving the feet are also recorded.[22]

A **malignant form** of the disease has also been observed in sheep. It begins with an acute episode manifested by oral vesicles, and extension of these lesions down the gastrointestinal tract, followed later by granulomatous lesions and shedding of hooves.

An atypical case of the disease in sheep after extensive cutaneous thermal injury has been described.[23] The virus was present in proliferative verrucous tissue lesions at the periphery of the original thermal injury.[23] The lesions consisted of tightly packed 0.5 mm-diameter papillary projections.

22.2.1.5.2

Goats

An unusual case of contagious ecthyma in a group of female goats has been described.[24] 1419
Multifocal lesions occurred over the head, neck, thorax, and flanks of each animal. The 1420
lesions developed approximately 2 weeks after the animals returned from a local summer show at which the does were housed for 3 days in pens previously occupied by sheep. The lesions began as plaques, followed by epidermal proliferation and severe encrustation. Affected areas were discrete and approximately 2–7 cm in diameter. There were no lesions of the muzzle, lips, udder or teats. Recovery occurred uneventfully within 3–6 weeks without treatment. The skin crusts gradually dried and fell off, leaving areas of alopecia and depigmented skin. Regrowth of hair followed.

Persistent orf is recorded in a proportion of Boer goats following an outbreak. The disease in the majority of the animals in the herd was classical and ran a clinical course of 3–4 weeks but in 2% of animals it persisted for several months and lesions disseminated over the body. There were no particular distinguishing differences of the

virus genome to those of other orf viruses and the persistence was possibly a result of individual host susceptibility factors.[25,26]

22.2.1.6

CLINICAL PATHOLOGY

Electron microscopic identification of the virus is quick and generally reliable with multiple samples from an affected herd or flock. Virus can also be detected by PCR and restriction enzyme analysis of viral DNA and gene sequencing.[26,27] Recovered animals have a high level of neutralizing antibodies in their serum and this is detectable by a gel diffusion test and other serological tests but has little clinical value.

22.2.1.7

NECROPSY FINDINGS

In malignant cases there are irregularly-shaped lesions, with a hyperemic border in the oral cavity and the upper respiratory tract, with rare involvement of the mucosae of the esophagus, abomasum, and small intestine. Typical lesions are actually proliferative, with subsequent loss of centrally located cells creating an ulcer-like appearance. Microscopically, the hyperplastic epithelium contains swollen degenerate cells, some of which may house eosinophilic cytoplasmic inclusion bodies.

22.2.1.7.1

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed lesions (LM)
- **Virology** – vesicle fluid, scraping from lesion (EM).

22.2.1.7.1.1

DIFFERENTIAL DIAGNOSIS

In most outbreaks of ecthyma, the cases are sufficiently mild to cause no real concern about losses or about diagnosis.

Dramatic outbreaks of a very severe form of the disease may occur, however, and are likely to be confused with bluetongue. Very severe cases are also commonly seen in housed experimental sheep especially colostrum-free lambs.

Ulcerative dermatosis is sufficiently similar to cause confusion in diagnosis, but this disease has not been reported in many years.

Mycotic dermatitis usually occurs on woolled skin but lesions can occur on the lips and feet (strawberry foot rot), have a thick dry asbestos-like scab and are easily differentiated by laboratory culture.

Facial eczema is distinguished by diffuse dermatitis and severe edema and damage to the ears.

Papillomatosis (warts) need also to be considered in the differential diagnosis for the proliferative manifestations of contagious ecthyma, although warts are extremely uncommon in sheep.

Bluetongue is always accompanied by a high mortality rate, a severe systemic reaction, and lesions occur on the muzzle, the coronets, and extensively on the buccal mucosa. It is more common in adults than sucking lambs. Because it is transmitted by insect vectors, the morbidity rate is usually much less than the 90% commonly seen in contagious ecthyma.

Sheeppox may present a rather similar clinical picture, but the lesions are typical, there is a severe systemic reaction and heavy mortality rate.

Foot and mouth disease. The classic developed lesions of orf are easily differentiated from foot and mouth disease but the papular and vesicular stages seen early in the course of orf, particularly lesions in the mouth, can be difficult to differentiate especially when a prompt on-farm differentiation is required. The raised firm papular erosive nature of the lesion with the surrounding zone of hyperemia is a crucial differentiating feature in the field.[28]

22.2.1.8

TREATMENT

There is no specific treatment. Removal of the scabs and the application of ointments or astringent lotions are practiced but delay healing in most cases. The provision of soft, palatable food is recommended. The combined use of diathermy debridement and cryosurgery is claimed to be effective for the proliferative intraoral lesions in young lambs.[29]

22.2.1.9

CONTROL

In the early stages of an outbreak, the affected animals should be isolated and the remainder vaccinated. Vaccination is of little value when a large number of animals are already affected. Persistence of the disease in a pastured flock from year to year is common and in such circumstances the lambs should be vaccinated at 6–8 weeks of age. Vaccination when a few days old evokes a protective response, but prelambing vaccination of the ewe does not and is not recommended.[30] Vaccination of housed lambs should be timed to avoid the usual occurrence of the disease that has been observed in previous years.

The vaccine is prepared from a suspension of scabs in glycerol saline and is painted onto a small area of scarified skin inside the thigh, or by pricking the ear with a needle dipped in the vaccine. Vaccination is completely effective for at least 2 years, but the lambs should be inspected 1 week after vaccination to insure that local reactions have resulted. Absence of a local reaction signifies lack of viability of the vaccine or the existence of a prior immunity. The immunity is not solid until 3 weeks after vaccination. A small proportion of vaccinated lambs may develop mild lesions about the mouth because of nibbling at the vaccination site. The efficiency of this vaccine is greater than that of the standard commercial vaccine containing live attenuated virus.[31] As a further protective measure, removal of abrasive material from the environment is recommended but is not usually practicable. For live sheep being transported from Australia to the Middle East, it is suggested animals be vaccinated well in advance of shipment to allow immunity to develop, which is probably at least 3 weeks.

Because the vaccines are live virus vaccines, and shed scabs are contaminated, routine vaccination against orf in flocks that have not experienced the disease is not recommended.

Outbreaks have occurred from vaccine virus.

1421

22.2.2 PAPILLOMATOSIS (WARTS)

22.2.2.1 Synopsis

22.2.2.1.1 Etiology

Papillomaviruses. Host specific, and in cattle, some types have site and lesion-type specificity

22.2.2.1.2 Epidemiology

Occur in all countries in all species but most common in young cattle and horses. Transmission is by direct contact and fomites

22.2.2.1.3 Clinical findings

Solid outgrowths of epidermis, may be sessile or pedunculated. Most common type in cattle occurs on head and neck and has cauliflower-like appearance, but lesion site and appearance varies with papilloma type. In the horse, lesions are on the face and lips

22.2.2.1.4 Clinical pathology

None specific

22.2.2.1.5 Lesions

Papilloma or fibropapilloma

22.2.2.1.6 Diagnostic confirmation

Histology and DNA identification by PCR in biopsy or tissue scraping

22.2.2.1.7 Treatment

Removal by surgery or cryosurgery. Vaccination with autogenous vaccine

22.2.2.2

ETIOLOGY

Cutaneous warts in cattle, horses, sheep and goats are benign tumors induced by host-specific papillomaviruses. These infect epithelial cells causing hyperproliferative lesions that are benign, self-limiting and, in most cases, spontaneously regress. Differentiation of types is based on the histological features of the lesion and DNA identification by hybridization or PCR. There has been little research on the papilloma virus of horses or small ruminants, but in cattle six types have been identified: bovine papilloma virus (BPV)-1, BPV-2 and BPV-5, which cause fibropapillomas; and BPV-3, BPV-4 and BPV-6, which cause true epithelial papillomas.[1,2]

Cattle types show some site predilection or site specificity. Their detailed roles are:

- BPV-1 – frond fibropapillomas of teat skin and penile fibropapilloma
- BPV-1 and BPV-2 – fibropapilloma of the skin of the anteroventral part of the body including the forehead, neck and back, the common cutaneous wart
- BPV-2 – cauliflower-like fibropapillomas of the anogenital and ventral abdominal skin
- BPV-2 – associated with bladder cancer in cattle in association with the ingestion of bracken fern (*Pteridium* spp.)[3,4]
- BPV-3 – cutaneous papilloma
- BPV-4 – papilloma of the esophagus, esophageal groove, forestomachs and small intestine; this is capable of becoming malignant, particularly in animals fed bracken fern.[4–6] BPV-4 has site specificity to the upper alimentary tract
- BPV-5 – rice grain fibropapilloma on the udder. BPV-5 has also been demonstrated in cutaneous skin warts[7]
- BPV-6 – frond epithelial papillomas of the bovine udder and teats.

Although a single BPV type is detected in an individual papilloma, a single animal may have papillomas at different sites associated with different BPV types.[8]

Other papilloma of cattle that have regional distribution and may have separate antigenic identity are:

- Oral papillomas, mostly in adult cattle and apparently reaching a high incidence, up to 16% in some areas[9]; these are probably BPV-4[8]
- Papilloma of the larynx in steers
- Papillomavirus has been observed in squamous cell carcinoma of bovine eyes.[10]

Other skin lesions in which papillomavirus plays an etiological role are:

- Equine sarcoid which associated with BPV-1 and BPV-2
- Ear cancer of sheep.[11]

Papillomas in horses may be associated with a distinct equine papillomavirus.[12]

22.2.2.3 EPIDEMIOLOGY

22.2.2.3.1 Occurrence

Papillomatosis has an international occurrence in all animal species.

22.2.2.3.2 Origin of infection and transmission

The method of spread is by **direct contact** with infected animals, infection gaining entry through **cutaneous abrasions**. Virus can also persist on inanimate objects in livestock buildings and infect animals rubbing against them.[8]

Crops of warts sometimes occur around ear tags, at branding sites or along scratches made by barbed wire, and can be spread by tattooing implements, dehorning shears, and by procedures such as tuberculin testing.[13–16]

An extensive outbreak of perianal warts is recorded in beef heifers, the infection having been spread by rectal examination for pregnancy. A high prevalence of papillomas on the larynx of feedlot steers is ascribed to implantation of the virus in contact ulcers, which are also entry sites for *Fusobacterium nodosus* (a cause of calf diphtheria), so that the two diseases may occur in the one animal. An outbreak of periorbital papillomatosis in cattle is recorded in association with a heavy periorbital infestation with *Haematopinus quadripertusus*.[17]

22.2.2.3.3

Animal risk factors

All species may be affected but the disease is commonest in cattle and horses. With cattle, usually several animals in an age group are affected. Outbreaks have been recorded in sheep and goats,[13,18] but the disease is uncommon in sheep. It is also uncommon in pigs, usually affecting the genitalia. Amongst wildlife, it occurs in white-tailed deer (*Odocoileus virginianus*) and mule deer (*O. hemionus*).

22.2.2.3.3.1

Age

Cutaneous papillomas of the head and neck occur predominantly in young animals, the lack of susceptibility of adults to natural infection being ascribed to immunity acquired by apparent or inapparent infection when young. The occurrence of cutaneous warts and their severity can be influenced by factors that induce immunosuppression, and latent infection has converted to clinical disease with the administration of immunosuppressive agents.[8,19] Congenital infection is recorded in the foal and calf, but is rare.[20]

Alimentary papillomas associated with BPV-4 in cattle, rice grain teat papillomas associated with BPV-5 in cattle, and papillomas on the mammary glands of goats occur, or persist, at all production ages.

22.2.2.3.4

Experimental production

The supernatant from a suspension of wart tissue, injected ID, or applied to skin scarifications, is an effective means of experimental production of the disease.[8,19] Lesions are restricted to the site of inoculation. Cutaneous and oral papillomas have been transmitted in cattle, and cutaneous papilloma transmitted in sheep and horses. The incubation period after experimental inoculation in cattle is 3–8 weeks but is usually somewhat longer after natural exposure.

22.2.2.3.5

Economic importance

Cutaneous warts are quite common in young cattle, especially when they are housed, but ordinarily they cause little harm and regress spontaneously. In purebred animals they may interfere with sales and shows because of their unsightly appearance. Animals with extensive lesions may lose condition, and secondary bacterial invasion of traumatized

warts may cause concern. Warts on the teats of dairy cows often cause interference with milking. In horses, the lesions are usually small and cause little inconvenience, but they are esthetically unattractive. In all species, the development of warts on the genitalia requires immediate treatment. 1422

22.2.2.4

PATHOGENESIS

The virus infects the basal keratinocytes, replicating its genome in the differentiating spinous and granular layers causing the excessive growth that is characteristic of wart formation. Expression of the late structural proteins of the virus is limited to the differentiated cells of the squamous layer where the new virus particles are encapsulated and shed into the environment as the cells die. The tumor contains epithelial and connective tissues and can be a papilloma or a fibropapilloma, depending on the relative proportions of epithelial and connective tissue present; papillomas contain little connective tissue, and fibropapillomas are mostly fibrous tissue, with very little epithelial tissue. Papillomas are the result of basal cell hyperplasia without viral antigen production. fibropapillomas are uncommon in horses, but are the common lesion in cattle, sheep, and wild ruminants.[21] Latent infection in the skin and lymphocytes has been demonstrated in cattle.[8]

22.2.2.5

CLINICAL FINDINGS

Warts are solid outgrowths of epidermis and may be sessile or pedunculated.

22.2.2.5.1

Cattle

In cattle, warts occur on almost any part of the body, but when a number of animals in a group is affected it is common to find them all affected in the same part of the body. The most common papillomas occur in the skin of cattle under 2 years of age, most commonly on the head, especially around the eyes, and on the neck and shoulders, but may spread to other parts of the body. They vary in size from 1 cm upwards and their dry, horny, cauliflower-like appearance is characteristic. In most animals they regress spontaneously, but the warts may persist for 5–6 months, and in some cases for as long as 18 months, with serious loss of body condition.

Warts on the **teats** manifest with different forms depending on the papilloma virus type and may show an increasing frequency with age. The **frond form** have filiform projections on them and appear to have been drawn out into an elongated shape of about

1 cm in length by milking machine action. If sharp traction is used they can often be pulled out by the roots.

Other forms are a flat, round type which is usually multiple, always sessile and up to 2 cm in diameter. The third form has an elongated structure appearing like a **rice grain**. Teat warts may regress during the dry period and recur with the next lactation.

Perianal warts are esthetically unattractive, but do not appear to reduce activity or productivity. **Genital warts** on the vulva and penis make mating impracticable because the lesions are of large size, are friable, and bleed easily. They commonly become infected and flyblown. They occur on the shaft or on the glans of the penis in young bulls, may be single or multiple, are pedunculated and they frequently regress spontaneously.

Alimentary tract warts are rarely observed clinically in farm animals in most countries, but are recorded in abattoir cattle at a high incidence in some localities[9] and have been reproduced experimentally.[8] Papillomas occur on the lateral and dorsal aspects of the tongue, the soft palate, oropharynx, esophagus, esophageal groove, and rumen. Papillomas occurring in the esophageal groove and in the reticulum are a cause of chronic ruminal tympany.

Less common manifestations of papillomatosis in cattle include lesions in the **urinary bladder**, which cause no clinical signs but may predispose to enzootic hematuria. BPV-4 papillomas in the upper alimentary tract of cattle being fed bracken fern are the focus for transformation to squamous cell carcinomas. Cattle fed bracken fern are immunosuppressed, which promotes the persistence and spread of the papilloma virus, and mutagens in bracken fern cause neoplastic transformation of papilloma cells.[4]

22.2.2.5.2

Goats

Papillomas most commonly occur on the face and ears but may occur on the skin generally, especially on unpigmented skin. Most completely regress, others regress and recur, and occasional lesions progress to carcinomas. Papillomas that occur on the teats are persistent and may spread through the herd.

22.2.2.5.3

Horses

Warts are confined to the lower face, the muzzle, nose and lips, and are usually sessile and quite small, rarely exceeding 1 cm in diameter. They may also occur on the penis and vulva, in the mouth, and on the conjunctiva. All ages can be affected. Spontaneous recovery is usual, but the warts may persist for 5–6 months.

22.2.2.6

CLINICAL PATHOLOGY

There are no specific changes in the hemogram or blood chemistry but cattle with papilloma have lower numbers of CD2 and CD4 lymphocyte subpopulations and higher numbers of gamma/delta+ T-lymphocytes and lymphocytes expressing IgM molecules.[22]

Biopsy of a lesion can be used, but is rarely necessary to confirm a diagnosis. However, it may be advisable when large growths are found on horses in order to determine if the lesion is a verrucose form of sarcoid. Microscopically, true papillomas consist of a hyperplastic epidermis with scant dermal tissue, whereas in fibropapillomas the dermal component tends to predominate. The need to identify the specific virus in a crop of warts creates a requirement for serological and histological examinations. An ELISA is available but BPV type can be determined by PCR on biopsy material or tissue scrapings[7] and is more accurate where a wart problem occurs in a vaccinated population.

22.2.2.6.1

DIFFERENTIAL DIAGNOSIS

Clinically, there is little difficulty in making a diagnosis of papillomatosis with the possible exception of atypical papillomas of cattle, probably associated with an unidentified type of the papillomavirus. These lesions are characterized by an absence of dermal fibroplasia, and are true papillomas rather than fibropapillomas. All ages of animals can be affected and the lesions persist for long periods. They are characteristically discrete, low, flat and circular, and often coalesce to form large masses. They do not protrude like regular warts and the external fronds are much finer and more delicate.

Horses:

- Sarcoid
- Melanoma.

22.2.2.7

TREATMENT

Warts can be removed by surgery or cryosurgery. Crushing of a proportion of small warts, or the surgical removal of a few warts, has been advocated as a method of hastening regression but the tendency for spontaneous recovery makes assessment of the results of these treatments very difficult. Partial resection of a wart(s) in a horse does not always promote resolution of the residue.[23] Surgical removal can be followed by vaccination with an autogenous vaccine. Surgical intervention, and even vaccination, in the early stages of wart development may increase the size of residual warts and prolong the course of the disease.

22.2.2.7.1

Vaccination

For cattle, autogenous vaccines prepared from wart tissues of the affected animal are effective in many cases. Commercially available vaccines are available for cattle but may be less efficacious; an autogenous vaccine prepared for a specific problem has the advantage of including the local virus types. The vaccine is prepared from homogenized wart tissue that is filtered and inactivated with formalin. Because of the different BPV types, care is required in the selection of the tissues. In general terms they can be selected on tumor type, location, and histological composition. The alternative is to use many types of tissue in the vaccine. Animal to animal variation in regression following vaccination of a group of calves with a vaccine prepared from a single calf in the group has been attributed to more than one BPV type producing disease in the group.[24] The stage of development is also important, and virus is present in much greater concentration in the epithelial tissue of older warts than young ones.[2] The vaccine can be administered SC, but better results are claimed for ID injection. Dosing regimes vary, but 2–4 injections 1–2 weeks apart are commonly recommended. Recovery in 3–6 weeks is recorded in 80–85% of cases where the warts are on the body surface or penis of cattle, but in only 33% when the warts are on the teats. The response of low, flat, sessile warts to vaccination is poor.

1422
1423

Other treatments no longer commonly used include the injection into the wart of proprietary preparations containing antimony and bismuth or the intralesional injection of bacille Calmette–Guérin (BCG).[25]

22.2.2.8

CONTROL

Specific control procedures are usually not instituted or warranted because of the unpredictable nature of the disease and its minor economic importance.

Vaccination has been shown experimentally to be an effective prevention and gives complete protection in cattle against stiff experimental challenge.[26] The vaccine must contain all serotypes of the papillomavirus because they are very type-specific.[27]

Avoidance of close contact between infected and uninfected animals should be encouraged, and the use of communal equipment between affected and unaffected animals should be avoided.

22.2.3 ## SARCOID

22.2.3.1 ### Synopsis

22.2.3.1.1 #### Etiology

Locally aggressive benign fibroblastic tumors of the skin associated with bovine papillomavirus BVP1 and BVP2

22.2.3.1.2 #### Epidemiology

Common tumor of horses, donkeys and mules. Breed differences in prevalence. Transmission by close contact and infection of wounds

22.2.3.1.3

Clinical findings

Single or multiple lesions in the skin of limbs, lips, eyelids, eye, penile sheath, and base of the ears. May present as warty growth or have the appearance of granulation tissue or as nodules beneath the skin. Spontaneous regression is rare

22.2.3.1.4

Diagnostic confirmation

Histopathology

22.2.3.1.5

Treatment

No single treatment modality has an advantage. Surgical excision, cryosurgery, immunotherapy, radiation, and local chemicals are used

22.2.3.1.6

Control

None recognized

22.2.3.2

ETIOLOGY

The cause of sarcoid in horses, mules, and donkeys is almost certainly bovine papilloma virus (BPV) types 1 or 2.[1–3] DNA of both types can be demonstrated in sarcoid tumors by PCR, as can the major transforming gene of BPV, E5, although papillomavirus has not been isolated from these tumors, nor have papillomavirus particles been demonstrated.[4–6] It is assumed that this is a non-productive infection in which viral DNA exists episomally.[3]

However, given the demonstration of genetic susceptibility to sarcoid, the cause is almost certainly multifactorial, with virus infection being an inciting event in susceptible animals.[7] There does not appear to be a role for mutation in the tumor suppressor gene, *p53*, in the development of sarcoid in horses.[8]

22.2.3.3

EPIDEMIOLOGY

22.2.3.3.1

Occurrence and prevalence

Equine sarcoid is the **commonest neoplasm** in horses, representing about 20% of all equine tumors diagnosed at necropsy. Horses, donkeys, and mules are affected. Sarcoid

tumors occur in 0.7% of Swiss warmblood, and 0.4% of Freiberger horses in Switzerland.[1] Of the horse **breeds**, Appaloosa, Arabian, and Quarter horses are at more risk than are Standardbreds or Thoroughbreds.[9]

22.2.3.3.2

Methods of transmission

Transmission can be by infection of wounds and castration is believed a risk factor, with flies as possible vectors.[10] Close contact may facilitate transmission.[2] BPV DNA has been detected in face flies (*Musca autumnalis*) associated with horses with sarcoids.[3]

22.2.3.3.3

Experimental reproduction

The disease has been transmitted with sarcoid tissue and cell free supernatant from minced sarcoid tumors. The disease has also been reproduced with bovine papillomavirus although the experimentally produced tumors subsequently regressed which seldom occurs with natural sarcoid.[3]

22.2.3.3.4

Animal risk factors

There is a **genetic-based susceptibility** to the disease,[7] and the predisposition of horses to sarcoid is associated with the type of **major histocompatibility complex**.[11] Approximately 40% of the susceptibility to the disease in Swedish Halfbred horses is attributable to an autosomal, dominant equine leukocyte antigen (ELA)-linked gene.[7] The prevalence in quarter horses is greater than that in thoroughbreds, and in both is higher than that in standardbreds.[9] Sarcoids are very rare in horses less than 1 year of age, and the prevalence is highest in horses 1 to 6 years-of-age. Young males appear more at risk, possibly related to castration.[10]

22.2.3.3.5

Environmental risk factors

Lesions commonly occur on traumatized areas.

22.2.3.4

PATHOGENESIS

Sarcoids are localized proliferations of epidermal and dermal tissue which may remain small and dormant for many years and then undergo a stage of rapid cancer-like growth. The lesions show moderate malignancy but do not metastasize to other sites, although

there may be multiple cutaneous lesions. The virus infects fibroblasts and the infection is non-productive. It is believed that virus capsids of BVP are not found in equine sarcoids because papillomavirus are usually host specific and the expression of virus capsids of the bovine papillomavirus requires the cellular environment of keratinocytes of the host species.[3] Sarcoids do not regress, in contrast to the majority of papillomavirus infections, probably because expression of BPV in equine cells elicits immune evasion mechanisms.[12]

1423 1424

22.2.3.5

CLINICAL FINDINGS

Sarcoids occur as single, or more commonly, multiple lesions or clusters in the skin. The lesions occur most commonly on the lower limbs but also on the lips, eyelids, eye, penile sheath, and around the base of the ears.

Several forms of sarcoid are described:[13]

- Verrucous (warty) sarcoid is a dry, horny, cauliflower-like surface that is usually partially or completely hairless. It may be broad based (sessile) or pedunculated. Verrucous sarcoids occur most commonly on the face, body, groin and sheath area. It has a predilection
- Fibroblastic sarcoid has a similar appearance to that of proud flesh or excessive granulation tissue. It is often a firm, fibrous nodule in the dermis, although the surface may be ulcerated. It is found most commonly at sites of previous wounds and also the eyelid and limbs
- A combination of both of the forms described above
- Occult sarcoid is typically an area of slightly thickened skin that has a roughened surface. It is usually partially hairless. Interference with these slow-growing sarcoids, including attempts at treatment, should be avoided; as such interference can cause the tumor to proliferate. They occur most commonly around the mouth and ayes and on the neck.

22.2.3.6

CLINICAL PATHOLOGY

Confirmation of the diagnosis requires a **biopsy specimen** for histologic examination. Because sarcoids are usually associated with excessive granulation tissue and pyogranulomatous debris, the preferred specimen is a **transverse section of the excised tumor**. If punch biopsies are to be collected, then care should be taken that they include a

representative section of the tumor, and not just peripheral granulation tissue and edematous non-tumor material. Examination by a pathologist accustomed to examining equine skin sections is important, as the tumor has some features in common with papillomas and sarcomas and may be easily misdiagnosed.

PCR has been used to detect BPV DNA but the sensitivity is less than optimal.[4,5]

22.2.3.6.1

DIFFERENTIAL DIAGNOSIS

- Cutaneous habronemiasis
- Phycomycosis
- Fibromas
- Granulation tissue
- Squamous cell carcinoma, especially of the penis and eyelid
- Other skin tumors, including melanoma by examination of a biopsy of the lesion
- Papillomatosis is a disease of young horses, and unlike sarcoid, commonly spontaneously regresses.

22.2.3.7

TREATMENT

Surgical excision results in the return of the tumor in a significant proportion of animals within 6 months, often with over proliferation. BPV DNA can be detected in normal skin immediately surrounding sarcoids and the recurrence reflects activation of latent BPV in normal tissue surrounding the tumor.[14]

Cryotherapy is associated with a much lower recurrence rate[1] but its use is limited by the anatomical location of the tumor. For instance, cryotherapy is not recommended for periocular lesions because of the risk of damaging nearby ocular tissues. The efficacy of cryotherapy may be enhanced by the use of thermocouples to monitor the temperature of the lesion to insure adequate freezing. At least two or three freeze–thaw cycles are necessary.

Radiation therapy using radon-222, gold-198, radium-226, cobolt-60 or iridium-192 has been used and is indicated for recurrent or surgically inaccessible sarcoids such as

periocular sarcoid.[15,16] Radiation therapy is also useful for treating sarcoids of the body and legs.[17] Local hyperthermia induced by a radiofrequency current of 2 MHz is also reported to be effective.[18]

Immunotherapy, by injection of live organisms, killed bacilli, or cell wall extract of the bacillus of Calmette and Guerin (BCG) have been successful on occasion, but their efficacy depends on the size of the lesion, its anatomical location, and possibly its type.[1] Immunotherapy may work by inducing tumor-specific immunity. Side-effects include local reactions characterized by edema and systemic anaphylactoid reactions after the second or third injections if commercial, whole-cell vaccines are used. Vaccines composed of cell-wall fractions in oil are free of such reactions and have given good results in periocular lesions, but sarcoids of the axilla did not react favorably.[19] Large sarcoids or cases with multiple lesions may also respond poorly.[20] Immunotherapy using mycobacterial cell wall skeleton combined with trehalose dimycolate has resulted in total tumor regression.[21]

Autogenous vaccines may result in the regression of existing sarcoids but have risk of inducing new tumors and are not recommended for routine therapy.[16]

A variety of chemical agents have been used for treatment but there are no controlled trials.[16]

As yet, no single treatment modality is universally successful in the treatment of sarcoid. In a study in 92 horses comparing outcome, a successful outcome was obtained in 79% of horses treated with cryosurgery, 67% of those treated with BCG vaccination, 82% of those treated with conventional excision and 71% of those treated using carbon dioxide laser.[22]

22.2.4 ## LUMPY SKIN DISEASE (KNOPVELSIEKTE, LSD)

22.2.4.1 ### Synopsis

22.2.4.1.1 #### Etiology

Lumpy skin disease virus, of the genus *Capripoxvirus*

22.2.4.1.2

Epidemiology

Enzootic in sub-Saharan Africa and Middle East with recent incursion into Israel. Epizootics interspersed with periods of sporadic occurrence. Transmission by contact and arthropod vector

22.2.4.1.3

Clinical findings

Fever, nodular lesions on the skin and mucous membranes and lymphadenopathy. Proportion of cattle develop generalized infection with high mortality

1424

1425

Clinical pathology Intracellular, eosinophilic inclusion bodies in biopsy material. Virus isolation. Fluorescent antibody and serum neutralization tests

22.2.4.1.4

Necropsy findings

Nodules in skin, upper alimentary, respiratory tract

22.2.4.1.5

Diagnostic confirmation

Biopsy and histology. Virus isolation

22.2.4.1.6

Treatment

Supportive

22.2.4.1.7

Control

Vaccination

22.2.4.2

ETIOLOGY

Lumpy skin disease (LSD) is a severe, systemic disease of cattle associated with the Neethling poxvirus, a **capripoxvirus**. It has close antigenic relationship to sheeppox and goatpox viruses which are also in the same genus. There appears to be a difference in virulence between strains.

22.2.4.3

Epidemiology

22.2.4.3.1

Occurrence

The disease used to be confined to sub-Saharan Africa, but it is now enzootic in Egypt, and has occurred in Israel[1] where it was eradicated by slaughter of infected and in-contact animals. Some field outbreaks are associated with severe and generalized infections and a high mortality, while with others there are few obviously affected animals and no deaths but in general outbreaks are more severe with the initial introduction of the infection to a region and then abate, probably associated with the development of widespread immunity. **Morbidity rates** reach 80% during epizootics, but are nearer 20% in enzootic areas. Morbidity rates of 31% are recorded in Egypt, and a morbidity of 10% in the recent incursion into Israel.[1] In Kenya, the disease is characterized by a much lower morbidity rate and the disease is much milder. **Case fatality rates** average 2%, but vary with the outbreak. Israel has experienced no direct mortality from the disease. There has been a resurgence of the disease in South Africa in the past decade probably due to higher rainfall and a decrease in the use of vaccination consequent to a previously low incidence.[2]

22.2.4.3.2

Origin of infection and transmission

Cattle can be infected by drinking water, but ingestion and direct contact transmission are not common routes, even though the virus is present in nasal and lacrimal secretions, semen, and milk of infected animals. Most cases are believed to result from transmission by an **arthropod vector**. Historically, LSD virus has been isolated from *Stomoxys calcitrans* and *Musca confiscata* and transmitted experimentally using *S. calcitrans* but other vectors are also suspect including *Biomyia, Culicoides, Glossina and Musca* spp. However, in a recent study, despite the detection of virus in mosquitoes (*Anopheles stephensi*, *Culex quinquefascuatus*) the stable fly and a biting midge (*Culicoides nebeculosis*) after they had fed on cattle with lumpy skin disease, the infection did not transmit to susceptible cattle when these arthropods were allowed to re-feed on them.[3]

22.2.4.3.3

Risk factors

22.2.4.3.3.1

Animal risk factors

All ages and types of cattle are susceptible to the causative virus, except animals recently recovered from an attack, in which case there is a solid immunity lasting for about 3 months. In outbreaks, very young calves, lactating and malnourished cattle develop more severe clinical disease.[2]

British breeds, particularly Channel Island breeds, are much more susceptible than zebu types, both in numbers affected and the severity of the disease. **Wildlife species** are not affected in natural outbreaks, although there is concern that they might be reservoir hosts. Typical skin lesions, without systemic disease, have been produced experimentally with Neethling virus in sheep, goat, giraffe, impala, and Grant's gazelle, but wildebeest were resistant. Serological evidence of naturally acquired infection has been observed only in African buffalo (*Syncerus caffer*).[4] There is only one report of the natural occurrence of LSD in a species other than cattle, in water buffalo (*Bubalis*), but no further such cases are recorded.

22.2.4.3.3.2

Environmental risk factors

Outbreaks tend to follow waterways and extensive epizootics are associated with high rainfall and concomitant high levels of insect activity with a peak of disease in the late summer and early autumn.[2]

22.2.4.3.3.3

Pathogen risk factors

Capripox viruses are generally resistant to drying, survive freezing and thawing. Resistance to heat is variable but most are inactivated at temperatures above 60°C.

22.2.4.3.4

Experimental production

Experimental transmission can be accomplished using ground-up nodular tissue and blood, or tissue culture virus. Disease is produced following intranasal, ID or IV challenge.[5] While lumpy skin disease is characterized by generalized nodular skin lesions, less than 50% of natural or experimental infections develop generalized skin

nodules and the length of the viremic period does not correlate with the severity of the clinical disease.

22.2.4.3.5

Economic importance

The mortality rate is low, but the economic loss is high. In all cattle there is severe loss of milk production and the occurrence of secondary mastitis predisposed by the development of lesions on the teats. Loss also occurs from damage to hides, the loss of bodily condition during the course of the disease, and the loss of fertility in affected bulls. Cow may abort in the course of the disease. Lumpy skin disease is considered to be one of the high risk diseases for spread out of Africa to the outside world and a potential agent of agroterrorism.

22.2.4.4

PATHOGENESIS

In the generalized disease there is viremia accompanied by a febrile reaction, and localization in the skin occurs with development of inflammatory nodules. In the experimental disease, following ID inoculation, local lesions can develop at the site of challenge without viremia and generalization of the infection.[5]

22.2.4.5

CLINICAL FINDINGS

An **incubation period** of 2–4 weeks is common in field outbreaks and 7–14 days following experimental challenge.[5] In severe cases there is an initial rise of temperature, which lasts for over a week, sometimes accompanied by lacrimation, nasal discharge, salivation, and lameness. **Multiple nodules** appear suddenly about a week later, the first ones usually appearing in the perineum. They are round and firm, varying from 1 to 4 cm in diameter, and are flattened and the hair on them stands on end. They vary in number from a few to hundreds; they are intradermal and, in most cases, are confined to the skin area. Other manifestations that may be observed in severe cases include lesions in the nostrils and on the turbinates, causing mucopurulent nasal discharge, respiratory obstruction and snoring; plaques, later ulcers, in the mouth causing salivation; nodules on the conjunctiva, causing severe lacrimation, and on the prepuce or vulva, and spreading to nearby mucosal surfaces. The limbs may become grossly distended with edema fluid.

In most cases the nodules disappear rapidly, but they may persist as hard lumps or become moist, necrotic, and slough.

Lymph nodes draining the affected area become enlarged and cause local edema. When sloughing of the yellow center of nodules occurs there is often exposure of underlying tissues, e.g. testicles or tendons. Lesions where skin is lost may remain visible for long periods, and where lesions have coalesced, large areas of raw tissue may be exposed. The skin lesions provide an excellent point of entry for screw worms. Pneumonia is a common sequel in cases where lesions occur in the respiratory tract.

A convalescence of 4–12 weeks is usual. Pregnant cows may abort.

22.2.4.6

CLINICAL PATHOLOGY

Antigen detection. Diagnosis is most commonly made by electron microscopic demonstration of typical capripox virions in full thickness skin biopsies or scabs coupled with the clinical findings of a generalized nodular skin disease with enlarged superficial lymph nodes. Biopsy of lesions reveals a granulomatous reaction in the dermis and hypodermis. In the earlier acute stages, there are intracellular, eosinophilic **inclusion bodies**.[6] Virus can be cultivated from lesions. Antigen can also be detected by antigen detection ELISA with samples taken early in the course of the disease before the development of neutralizing antibodies and by fluorescent antibody tests and PCR. The AGID test can be used but the antigen will also react with parapox virus. A recent study in experimentally infected cattle found that virus in skin lesions could be detected by PCR for 90 days after infection, much longer than detection by virus isolation.[7]

1425 1426

Serology. Virus neutralization the indirect fluorescent antibody tests are commonly used. AGID tests may give false-positive reactions due to cross reaction with bovine papular stomatitis virus and pseudocowpox virus.

22.2.4.7

NECROPSY FINDINGS

The cutaneous lesions are described under clinical pathology. Similar lesions are present in the mouth, pharynx, trachea, skeletal muscle, bronchi and stomachs, and there may be accompanying pneumonia. The superficial lymph nodes are usually enlarged. Respiratory distress and death are often the result of respiratory obstruction by the necrotic ulcers and surrounding inflammation in the upper respiratory tract and/or concurrent aspiration pneumonia. Histologically, a widespread vasculitis reflects the viral tropism for endothelial cells. Intracytoplasmic viral inclusion bodies may be seen in a variety of cells types.

22.2.4.7.1

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed lesions from skin, alimentary and respiratory tissue, lymph node (LM)
- **Virology** – lymph node, skin lesion (ISO).

22.2.4.7.1.1

DIFFERENTIAL DIAGNOSIS

The rapid spread of the disease and the sudden appearance of lumps in the skin after an initial fever make this disease quite unlike any other affliction of cattle.

Pseudo-lumpy skin disease (also known as Allerton virus infection and 'general infection of cattle with bovine herpesvirus-2'), is associated with bovine herpesvirus-2, the agent of bovine mammillitis. It occurs primarily in southern Africa, but very occasional cases are recorded in the United States, Australia, and the United Kingdom[8–10] and is stated to occur more commonly in the southern United States than formally recognized.[10] Multifocal lesions are distributed over the body, and are circular, up to 2 cm in diameter, with loss of hair and an intact central area and raised edges. Some lesions show a circular ring of necrosis around a central scab. The scabs fall off leaving discrete hairless lesions that may be depigmented. The disease runs a course of approximately 2 weeks and there is no mortality. Only the superficial layers of skin are involved. This is in contrast to the lesions of lumpy skin disease, which are often deep enough to expose underlying tissues. Herpesvirus can be isolated from the periphery of the lesions. Diagnosis can be made by PCR on full-thickness skin biopsy.[10]

22.2.4.8

TREATMENT

No specific treatment is available, but prevention of secondary infection is essential. The use of antibiotics or sulfonamides is recommended.

22.2.4.9

CONTROL

Lumpy skin disease moves into new territory principally by means of the movement of infected cattle or possibly by wind-borne vectors.[1] In the new territory further spread is accepted as being via an insect vector. Control of cattle movement from uninfected to

infected territory is an important control measure. Further control can only be by vaccination.

22.2.4.9.1

Vaccination

A safe and effective vaccine has been produced by 60 passages of the virus through lamb kidney culture. It is administered to all animals over 6 months of age and is effective, but is associated with considerable local reaction that may persist over 1 month and may predispose fly strike. Local response to the vaccine is usually correlated with good antibody reponse.[2] A freeze-dried, living attenuated virus vaccine is also available. Vaccination of cattle with sheeppox virus, also attenuated by passage through tissue culture, is effective in preventing infection with the lumpy skin disease virus and is currently the most common method of protection.[11,12] A small percentage of cattle develop granulomatous local reactions but there is no spread of the sheeppox to sheep running with the cattle. Vaccination of a herd at the start of an outbreak has limited efficacy as most animals will already be incubating the disease. Poor needle hygiene in these circumstances may spread the disease.

Cattle vaccinated with a recombinant capripox-rinderpest vaccine are immune to experimental challenge with both viruses but for a different length of time with each agent.[13]

Slaughter of affected and in-contact animals and destruction of contaminated hides, coupled with vaccination of at-risk animals, is used when the disease gains access to a previously free country.

22.2.5

VIRAL PAPULAR DERMATITIS

This disease of horses occurs in the United States, United Kingdom, and Australia. It is a contagious disease characterized by cutaneous lesions in the form of firm papules 0.5–2 cm in diameter. No vesicles or pustules are formed, but after 7–10 days a dry crust is detached, leaving small circumscribed areas of alopecia. The lesions are not itchy, there is no systemic disease and the distribution of the lesions, and the way in which they can develop simultaneously in large numbers in introduced horses, is suggestive of an insect-borne disease.

The course of the disease varies between 10 days and 6 weeks. An unidentified virus has been isolated from lesions and cultured on eggs. A febrile reaction, up to 40.2°C (104.5°F), precedes the appearance of skin lesions by about 24 hours. There is no histological description. Recovery is usually complete and uncomplicated. The disease is clinically similar to **molluscum contagiosum** in horses associated with poxvirus. This disease has similar papular lesions, which are hypopigmented and covered by tufts of raised hair but the disease has a long clinical course. Histologically, these show proliferation of keratinocytes

containing large intracytoplasmic inclusions, known as molluscum bodies, which are composed of numerous pox virions.

22.2.6 COWPOX

22.2.6.1 Synopsis

22.2.6.1.1 Etiology

Cowpox virus is a member of the genus *Orthipoxvirus* in the family Poxviridae

22.2.6.1.2 Epidemiology

Endemic infection of certain rodents in Europe and east Asia. Cattle are a rare and incidental host. Spread in cattle by contact

22.2.6.1.3 Clinical findings

Typical pox lesions on the teats and udder. Erythema, papules with a zone of hyperemia around the base, vesiculation, pustular stage and scab

22.2.6.1.4 Clinical pathology

Electron microscopy

22.2.6.1.5 Diagnostic confirmation

Electron microscopy and virus isolation

22.2.6.1.6 Treatment

Palliative

22.2.6.1.7 Control

Sanitation to prevent spread between cows

22.2.7 ETIOLOGY

Cowpox virus is a member of the genus *Orthipoxvirus* in the family Poxviridae. Other orthipoxviruses infecting agricultural animals include horsepox, Uasin Gishu, buffalopox and

camelpox.[1] All orthipoxviruses are antigenically extremely similar, but they can be identified by a combination of phenotypic and genetic tests.

22.2.7.1

EPIDEMIOLOGY

22.2.7.1.1

Occurrence

Cowpoxvirus could be considered to be misnamed. Infection with this virus is **endemic in wild rodents** such as voles (*Microtus* spp.) in **Great Britain, Europe and western Asia**, with infection in different rodent species acting as the reservoir host in different geographic areas.[2,3] Domestic cats are commonly infected from hunting rodents, but cowpoxvirus infection can occur in a number of different mammalian species,[2] one of which is cattle. The clinical syndrome of cowpox in **cattle** is now **extremely rare** but it occurs sporadically in Europe. Seroprevalence in British cattle is less than 1%.

22.2.7.1.2

Origin of infection and transmission

The origin of infection is most probably from infected farm cats or humans. **Transmission** from cow to cow within a herd is effected by milkers' hands or teat cups. Spread from herd to herd is probably effected by the introduction of infected animals, by carriage on milkers' hands, and in the absence of either of the above methods, transport by biting insects is possible. In a herd in which the disease is enzootic, only heifers and new introductions develop lesions. Milkers recently vaccinated against smallpox may serve as a source of infection for cattle, although the **vaccinia virus**, the smallpox vaccine virus, is a different virus.

It is generally assumed that the virus gains access to tissues through injuries to teat skin, and extensive outbreaks of cowpox are likely to occur when the environment is conducive to teat injuries. Spread is rapid within a herd and immunity is solid, so that the disease tends to occur in sharp **outbreaks** of several months' duration with subsequent immunity protecting the cattle for at least several years.

22.2.7.1.3

Economic importance

Losses are due to inconvenience at milking time because of the soreness of the teats and from occasional cases of mastitis, which develop when lesions involve teat sphincters. Milk from affected cows is suitable for human consumption.

22.2.7.1.4

Zoonotic implications

Human cowpox is not common and usually consists of one or a few lesions on the hand and face with minimal systemic reaction.[4] Infection is more likely to come from an infected cat than cattle.[4,5]

22.2.7.2

PATHOGENESIS

In cowpox, the five stages of a **typical pox eruption** can be observed. After an incubation period of 3–6 days, a roseolar erythema is followed by firm, raised papules light in color but with a zone of hyperemia around the base. Vesiculation, a yellow blister with a pitted center, follows. The subsequent pustular stage is followed by the development of a thick, red, tenacious scab.

In experimentally produced **vaccinia virus** mammillitis (produced by inoculation of smallpox vaccine), the lesions have three zones: a central brown crusty area of necrosis, surrounded by a gray-white zone of microvesicle formation, again surrounded by a red border due to congestion. The lesions are essentially hyperplastic.

22.2.7.3

CLINICAL FINDINGS

Typical **lesions** may be seen at any stage of development, but are mostly observed during the scab stage, the vesicle commonly having been ruptured during milking. True cowpox scabs are 1–2 cm in diameter and are thick, tenacious, and yellow-brown to red in color. In cows being milked, scab formation is uncommon, the scab being replaced by a deep ulceration.

Distribution of the lesions is usually confined to the teats and lower part of the udder. Soreness of the teats develops and milk letdown may be interfered with; the cow usually resents being milked. Secondary mastitis occurs in a few cases. Individual lesions heal within 2 weeks, but in some animals fresh crops of lesions may cause the disease to persist for a month or more. In severe cases, lesions may spread to the insides of the thighs, and rarely to the perineum, vulva and mouth.[6] Sucking calves may develop lesions about the mouth. In bulls, lesions usually appear on the scrotum.

22.2.7.4

CLINICAL PATHOLOGY

The virus can be propagated in tissue culture, and differentiation is possible by electron microscopy.[7]

22.2.7.4.1

DIFFERENTIAL DIAGNOSIS

A number of skin diseases may be accompanied by lesions on the udder and can easily be confused with cowpox if the lesions are advanced in age. The differential points are listed in Table 22.2. Most outbreaks of teat skin disease that clinically resemble classical cowpox are associated with vaccinia virus from contact with a recently vaccinated person.

- Pseudocowpox
- Bovine ulcerative mammillitis associated with bovine herpesvirus-2 and bovine herpesvirus-4
- Vesicular stomatitis, and foot and mouth disease
- Udder impetigo
- Teat chaps and frostbite
- Black spot.

22.2.7.5

CONTROL

Prevention of spread is difficult, since the virus responsible for the disease is readily transmitted by direct or indirect contact. Udder cloths, milking machines and hands should be disinfected after contact with infected animals. Dipping of the teats in an alcoholic tincture of a suitable disinfectant, such as quaternary ammonium compounds, is usually satisfactory in preventing immediate spread. The prevalence and significance of the disease in cattle is too low to warrant the development of vaccines.[7]

22.2.8

PSEUDOCOWPOX (MILKERS' NODULE)

22.2.8.1

Synopsis

22.2.8.1.1

Etiology

Parapoxvirus

22.2.8.1.2

Epidemiology

Primarily affects cows in early lactation. Low, but progressive, morbidity in herd. Spread during milking

22.2.8.1.3

Clinical findings

1427

1428

Vesicles, pustules, formation of a thick scab elevated by granulating tissue. Horseshoe-shaped ring of small scabs surrounding granulating tissue

22.2.8.1.4

Clinical pathology

Vesicle fluid for electron microscopy

22.2.8.1.5

Diagnostic confirmation

Electron microscopy

22.2.8.1.6

Treatment

Antiseptics and emollient ointment

22.2.8.1.7

Control

Milking hygiene

22.2.8.2

ETIOLOGY

Pseudocowpox virus is a member of the genus *Parapoxvirus*, with close similarity to the viruses of infectious papular stomatitis and contagious ecthyma. It is possible that *Parapoxvirus* may be a single virus adapted to different species of ruminants.

22.2.8.3

EPIDEMIOLOGY

22.2.8.3.1

Occurrence

Pseudocowpox is reported from **most countries**. In an affected herd the rate of spread is relatively slow and may result in the disease being present in the herd for up to a year. The **morbidity** rate approximates 100%, but at any given time varies between 5 and 10%, and occasionally up to 50%.

22.2.8.3.2

Origin of infection and transmission

The source of infection is **infected cattle**. The method of **transmission** includes physical transport by means of contaminated milkers' hands, wash cloths, and teat cups. The virus cannot penetrate mucosa, and a pre-existing discontinuity of it is necessary for the virus to gain entry. Transmission by biting insects seems likely. The virus can be isolated from the mouths of calves sucking affected calves, and from the semen of bulls.

22.2.8.3.3

Animal risk factors

Freshly calved and **recently introduced** cattle are most susceptible, but **all adult cattle** in a herd, including dry cows, are likely to be affected. The disease does not appear to occur in animals less than 2 years of age unless they have calved. There is no seasonal variation in incidence. Little immunity develops and the disease is likely to recur in the herd within a short time.[1]

22.2.8.3.4

Economic importance

Pseudocowpox is relatively benign, most losses occurring as a result of difficulty in milking and an increase in the incidence of mastitis.

22.2.8.3.5

Zoonotic implications

The disease is transmissible to humans, infection usually resulting in the development of milkers' nodule on the hand.

22.2.8.4

PATHOGENESIS

The disease can be reproduced by the introduction of the virus onto scarified areas of skin. The lesions are characterized by hyperplasia of squamous epithelium.

22.2.8.5

CLINICAL FINDINGS

Acute and chronic lesions occur, and there may be up to ten lesions on one teat. **Acute lesions** commence as erythema followed by the development of a vesicle or pustule, which ruptures after about 48 hours, resulting in the formation of a thick scab. Pain is moderate and present only in the pre-scab stage. The scab, varying in size from 0.5 to 25 cm in diameter, becomes markedly elevated by developing granulating tissue beneath it; 7–10 days after lesions appear the scabs drop off, leaving a **horseshoe-shaped ring** of small scabs surrounding a small, wart-like granuloma, which may persist for months. The disease tends to disappear from a herd after 18–21 days but may recur cyclically about 1 month later. There are reports of lesions occurring occasionally in cows' mouths.

Chronic lesions also commence as erythema, but progress to a stage in which yellow-gray, soft, scurfy scabs develop. The scabs are readily rubbed off at milking, leaving the skin corrugated and prone to chapping. There is no pain and the lesions may persist for months.

Milkers' nodules are clinically indistinguishable from human lesions associated with ecthyma virus. The lesions vary from multiple vesicles to a single, indurated nodule.

22.2.8.6

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

Material for examination by tissue culture or electron microscopic examination, the latter being highly recommended as a diagnostic procedure, should include fluid from a vesicle.

22.2.8.6.1

DIFFERENTIAL DIAGNOSIS

Differentiation of those diseases in which lesions of the teat are prominent is dealt with in the preceding section on cowpox.

22.2.8.7 TREATMENT

Locally applied ointments of various kinds appear to have little effect on the lesions. The recommended treatment includes the removal of the scabs, which should be burned to avoid contaminating the environment, application of an astringent preparation, such as triple dye, after milking and an emollient ointment just before.

22.2.8.8 CONTROL

Recommended measures, such as treatment and isolation of affected cows, or milking them last, the use of disposable paper towels for udder washing, and disinfection of teat cups, appear to have little effect on the spread of the disease. An iodophor teat dip is recommended as the most effective control measure.[2] An effort should be made to reduce teat trauma because infection is facilitated by discontinuity of the skin.

22.2.9 BOVINE ULCERATIVE MAMMILLITIS (BOVINE HERPES MAMMILLITIS)

22.2.9.1 Synopsis

22.2.9.1.1 Etiology

Bovine herpesvirus-2, rarely bovine herpesvirus-4

22.2.9.1.2 Epidemiology

Occurs as an outbreak in cows, particularly heifers, usually within 2 weeks after calving. Commonly followed by persistent infection in the herd

22.2.9.1.3

Clinical findings

Lesions confined to teats and udder. Vesicles leading to sloughing of skin and necrotic ulceration. Prolonged clinical course

22.2.9.1.4

Clinical pathology

Virus isolation and electron microscopy on fresh lesions, serology

22.2.9.1.5

Treatment

Antiseptic and emollient ointments

22.2.9.1.6

Control

Isolation and milking hygiene, but not effective. Control of periparturient udder edema

22.2.9.2

ETIOLOGY

The causative virus, **bovine herpesvirus-2** (BHV-2), is an alphaherpesvirus. Infection with BHV-2 can produce two distinct syndromes in cattle, **bovine herpes mammillitis** where there are vesicular and erosive lesions with necrotic ulceration on the skin of the udder and teats and **pseudo-lumpy skin disease** (Allerton virus) manifest with generalized superficial skin lesions over the body. Pseudo-lumpy skin disease is uncommon. The difference in clinical manifestations between the two diseases may be due to the strain of the virus, or the method of infection. **BHV-4** (DN599 strain), which is usually associated with respiratory disease in cattle, is also capable of causing mammary pustular dermatitis.[1]

22.2.9.3

EPIDEMIOLOGY

22.2.9.3.1

Occurrence

Herpes mammillitis is recorded in North America, Australia, Europe and Africa, but probably has **widespread occurrence**. Herds infected for the first time have a high morbidity rate. Subsequently, the incidence is low and is limited to fresh heifers. The **morbidity** rate varies between 18 and 96%, susceptible herds recording more than 30% affected. The **mortality** rate is negligible.

1428
1429

22.2.9.3.2

Origin of infection and transmission

Introduction of bovine ulcerative mammillitis into a herd may occur with the introduction of infected animals, but outbreaks have been observed in self-contained herds. **Spread** within the herd is probably by direct and fomite-mediated transmission, although experimentally the virus must be deposited in the deep layers of the skin, and even rubbing it into pseudocowpox lesions is not an efficient way of transmitting the disease. Milking machine liners, hands, and udder cloths may act as carriers of virus when a large amount of it is being released.

Seasonal and circumstantial evidence in the **United Kingdom** and **Australia** suggest an insect vector, but this has not been confirmed by attempts at transmission with the stable fly (*Stomoxys calcitrans*), and in the mid-west of the **United States**, disease is more common in the winter months between November and April.[2]

Survival of the virus for long periods in carrier animals occurs and it is thought that this may be the means of survival of the virus within a herd that has become immune.[3] Infection in some cows is suspected to result in chronic infection at the teat end with the cows becoming '**hard milkers**' and **carriers** of the disease.[2]

22.2.9.3.3

Animal and pathogen risk factors

Lesions are most common in animals within the **first 2 weeks after calving**, particularly in **heifers**, and the disease is more severe in heifers. Heifers that have **udder edema** at calving are particularly prone to develop severe lesions. Occasionally, lesions may be seen on the teats of replacement heifers and calves sucking infected dams often develop mouth lesions.

The disease is **usually self-limiting**, persisting in a herd for 6–15 weeks, the severity of the lesions decreasing as the outbreak progresses. Immunity appears to last about a year, herds infected naturally can suffer recurrences a year later. **Large herds** may have **persisting** disease, particularly in heifers.

The virus is relatively resistant to environmental influences and can survive freezing. It is susceptible to **iodophor disinfectants** and less so to hypochlorites.

22.2.9.3.4

Economic importance

Forms of loss include a much higher incidence of mastitis, reduction in milk in affected herds by up to 20%, the **culling** of some cows because of severe mastitis and of heifers because of intractable ulcers, and a great deal of interference with normal milking procedure.

22.2.9.3.5

Zoonotic implications

There are anecdotal reports of herpetic lesions in farmers exposed to infected cattle.[4]

22.2.9.4

PATHOGENESIS

Typical clinical lesions and histopathological changes can be produced locally by introduction of the virus into scarifications of the skin of the teat and the oral mucosa, and by ID and IV injection. There is no viremia and spread is by local extension. In contrast to the poxes, the characteristic lesion in mammillitis is destructive. The higher incidence of the disease and the greater severity of the lesions close to calving are thought to be due to the immunosuppression caused by parturition and to greater predisposition from periparturient udder edema.

22.2.9.5

CLINICAL FINDINGS

There is an **incubation period** of 5–10 days. There is no systemic illness, and lesions are confined to the teats and udder. When the disease occurs in a herd for the first time the first case is usually in a cow that has calved during the previous 2–3 days. Rapid lateral spread then occurs to other cows.

In cows calved more than a few weeks previously, the characteristic lesions are almost entirely confined to the skin of the teats; in recently calved cows they are restricted to the skin of the teats and the udder. The severity of the disease in recently calved cattle appears to be directly proportional to the degree of postparturient edema which is present. **Vesicles** occur but are not commonly seen. They are characteristically thin-walled, 1–2 cm in diameter, variable in outline, and often commence at the base of the teat and spread over much of the udder surface. Rupture and confluence of the vesicles leads to weeping and extensive **sloughing** of the skin.

In the most **severe cases**, the entire teat is swollen and painful, the skin is bluish in color, exudes serum and sloughs, leaving a raw ulcer covering most of the teat. In less severe cases, there are raised, deep red to blue, circular plaques, 0.5–2 cm in diameter, which develop shallow ulcers. In most cases, scab formation follows but machine milking causes frequent disruption of them, resulting in frequent bleeding. The least severe lesions are in the form of lines of erythema, often in circles and enclosing dry skin or slightly elevated papules, which occasionally show ulceration. Mild lesions tend to heal in about 10 days but severe ulcers may persist for 2 or 3 months. The severity of lesions on the teats on longer-calved cows varies, but in all cases the lesions are sufficiently painful to make milking difficult. Lesions on the skin of the udder heal more rapidly because of the absence of trauma.

Ulcers in the mouth of affected cows have been observed rarely, and calves sucking affected cows develop lesions on their oral mucosae and muzzles. Ulcerative lesions on the vaginal mucosa have been recorded rarely. During the recovery phase there is obvious scar formation and depigmentation.

The generalized skin disease associated with BHV-2, '**pseudo-lumpy skin disease**' is discussed in the differential diagnosis of lumpy skin disease.

22.2.9.6

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

Material for tissue culture, electron microscopy, or cutaneous transmission tests is best obtained by syringe from early vesicles, or as swabs from early ulcers or oral lesions. The virus may be difficult to demonstrate if the lesions are as old as 7 days, and if there has been intensive application of teat disinfectants such as iodophors.

Serology is more commonly used for diagnosis. The presence of high virus-neutralizing antibody titers in serum taken during the acute phase of the disease, and a four-fold increase or decrease in titer in paired samples, are all supportive for diagnosis.[3,5] Titers of 1:16 or higher for BHV-2 and 1:20 for BHV-4 indicate exposure. Antibody to both viruses should be tested for diagnostic purposes.[2]

Necropsy is not commonly performed and no necropsy reports of cases of bovine ulcerative mammillitis are available.

22.2.9.6.1

DIFFERENTIAL DIAGNOSIS

Differentiation of other diseases of the skin of the teat and udder is dealt with in the section on cowpox.

22.2.9.7

TREATMENT

There is no specific treatment and the aim should be to develop scabs that can withstand machine milking. This is most easily effected by the application of a water-miscible, antiseptic ointment just before putting the cups on, followed by an astringent lotion, such as triple dye, immediately after milking. Crystal violet dyes have an excellent reputation as treatments.

22.2.9.8

CONTROL

Isolation of affected animals and strict hygiene in the milking parlor are practiced but have little effect on the spread of the disease, nor does milking heifers first. An **iodophor** 1429
disinfectant is recommended for use in the dairy to prevent spread. Reducing the incidence 1430
and severity of **periparturient edema** in heifers may reduce the severity of herpes mammillitis. Inoculation of the natural virus away from the teats produces a local lesion and good immunity, but the method has not been tested as a control procedure.

22.2.10 SHEEPPOX AND GOATPOX

22.2.10.1 Synopsis

22.2.10.1.1 Etiology

Capripoxvirus. Strains vary in virulence and host specificity

22.2.10.1.2 Epidemiology

Highly contagious, spread by aerosol, contact and flies. Young and non-indigenous animals more susceptible. Morbidity and case fatality rates are high

22.2.10.1.3 Clinical findings

Fever, generalized skin and internal pox lesions, lymphadenopathy, mucopurulent nasal discharge, high mortality

22.2.10.1.4 Clinical pathology

Fluorescent antibody and electron microscopy of biopsy material, serology, virus isolation

22.2.10.1.5 Necropsy findings

Pox nodular lesions in alimentary and respiratory tract

22.2.10.1.6 Diagnostic confirmation

Fluorescent antibody staining, virus isolation

22.2.10.1.7 Control

Vaccination

22.2.10.2 ETIOLOGY

Three viruses are named on the basis of their host specificity in natural outbreaks. **Sheeppox virus** and **goatpox virus** are mainly highly host specific in natural infections, but exceptions exist and **Kenya sheep and goatpox virus**, and Yemen and Oman sheep

isolates infect both sheep and goats. All are members of the genus *Capripoxvirus*, are closely related on the basis of genome mapping, and many cross species barriers in experimental infections[1–3] although not in natural occurrence. Recombination may occur naturally between isolates from different host species.[4,5] The diseases they produce are also collectively called **capripox infections**.[2]

22.2.10.3

EPIDEMIOLOGY

22.2.10.3.1

Occurrence and prevalence of infection

Sheeppox and goatpox are prevalent in North and Central Africa, the Indian subcontinent, Middle Eastern countries, China, Southwest Asia and the former Soviet Union. Sporadic outbreaks occur in southern Europe and elsewhere.[6] The capripoxvirus infections of small ruminants are the **most serious** of all the pox diseases in animals. In susceptible flocks and herds morbidity is 75–100% with outbreaks often causing death in 10–85% of affected animals depending on the virulence of the infecting strain.[2,6–9]

22.2.10.3.2

Methods of transmission

Sheeppox and goatpox are **highly contagious.** The virus enters via the respiratory tract and transmission commonly is by aerosol infection associated with close contact with infected animals. The virus is present in nasal and oral secretions for several weeks after infection and can live in scabs that have fallen off the animal for several months. Spread can also occur from contact with contaminated materials and through skin abrasions produced iatrogenically or by insects. Capripox has been shown to spread via the bites of *Stomoxys calcitrans* and the tsetse fly.[10]

22.2.10.3.3

Experimental reproduction

The disease can be transmitted by intradermal, intravenous and subcutaneous inoculation and by virus aerosols.

22.2.10.3.4 Risk factors

22.2.10.3.4.1 Animal risk factors

Both sheep pox and goat pox affect sheep and goats of all ages, breeds and sex but young and old animals and lactating females are more severely affected. In areas where sheeppox is enzootic, **imported breeds** such as Merinos or some European breeds may show greater susceptibility than the native stock. **Young animals** are more susceptible.

22.2.10.3.4.2 Pathogen risk factors

The virus is resistant to drying and survives freezing and thawing. It is sensitive to extremes of pH and 1% formalin. Sensitivity to heat varies between strains but most are inactivated at 60°C for 60 min.[6] Isolates from most regions are host specific but isolates from Kenya, Yemen and Oman naturally infect both goats and sheep. Scabs shed by infected animals remain infective for several months.

22.2.10.3.5 Economic importance

Loss is from mortality, abortions, mastitis, loss of wool, skin condemnation and loss of exports. In ewes and does, severe losses may occur if the udder is invaded because of the secondary occurrence of acute mastitis. In some outbreaks, adult sheep are affected with the more severe form of the disease.[11] Sheeppox is a potent threat to countries that have big sheep populations, and where the disease does not occur, because of its ineradicability and heavy mortality rate.

22.2.10.3.6 Zoonotic implications

Human infections in people handling infected animals are not a consideration.[6]

22.2.10.4 PATHOGENESIS

During an initial viremia, the virus is deposited in most tissues, including the skin. The development of typical pox lesions, as in vaccinia, is characteristic of the disease. The virus is present in greatest quantities between the 7th and 14th day after inoculation.

Passive protection by serum will protect against challenge. Circulating antibody limits spread of infection, but does not prevent replication of virus at the site of inoculation.

22.2.10.5

CLINICAL FINDINGS

In **sheeppox** in sheep there is an incubation period of 12–14 days. In lambs, the **malignant form** is the most common type. There is marked depression and prostration, a very high fever and discharges from the eyes and nose. Affected lambs may die during this stage before typical **pox lesions** develop. These, when they develop, occur on unwooled skin and on the buccal, respiratory, digestive, and urogenital tract mucosae. They commence as papules, then become nodular, occasionally become vesicular, pustular and finally scab. Some progress from nodules to tumor-like masses.[12] The mortality rate in this form of the disease may reach 50%. In the **benign form**, more common in adults, only skin lesions occur, particularly under the tail, and there is no systemic reaction and animals recover in 3–4 weeks. Abortion and secondary pneumonia are complications. Goatpox in sheep is more severe than sheeppox, and lesions occur on the lips and oral mucosa, the teats and udder.

Goatpox in goats is very similar clinically to sheeppox in sheep. Young kids suffer a systemic disease, with lesions spread generally over the skin, and on the respiratory and alimentary mucosae. Adult goats may have systemic disease and extensive lesions,[7,10] but in adult goats the disease is usually mild and lesions are as described above for the benign form in sheep. A flat hemorrhagic form of capripox is seen in some European goats and this has a high case fatality.

22.2.10.6

CLINICAL PATHOLOGY

22.2.10.6.1

Antigen detection

Diagnosis is based on typical clinical signs combined with laboratory confirmation of the presence of the virus or antigen. Using electron microscopy, large numbers of characteristic ‘sheeppox cells’ containing inclusion bodies and typical capripox virions can be seen in biopsies of the skin. The virus can be cultured in tissue culture but virus isolation as a method of rapid diagnosis is limited by the time it takes for virus cytopathic effects to develop and the need, with some strains, for several blind passages before this develops. Direct fluorescent antibody test is used to detect the presence of

1430

1431

pox virus in the edema fluid and the antigen can be detected in biopsies of lymph glands by AGID using specific immune sera. An antigen detection ELISA is also available.

22.2.10.6.2

Serology

In India a 'soluble antigen fraction', which is non infectious, has replaced infectious virus for serological tests which avoids the risk of accidental spread of the virus from diagnostic laboratories and from the postal supply of diagnostic agents.[6] However, serological tests such as AGPT, serum neutralization and agar gel diffusion are confounded due to cross reaction with orf virus. A capripox-specific capture-ELISA is reported to have sufficient sensitivity, specificity and speed to have utility in rapid diagnosis using biopsy samples.[13] Serological testing can be by virus neutralization, which is specific or by an indirect fluorescent antibody test or an agar gel precipitation (AGPT), however both of the latter cross react with antibody to contagious pustular dermatitis virus. Virus-specific analysis of antibody response by Western blot analysis can differentiate the infections.[14]

A capripox PCR for detection of antigen is used in some countries which do not have the disease and do not hold live virus.[15,16]

22.2.10.7

NECROPSY FINDINGS

In the malignant form, pox lesions extend into the mouth, pharynx, larynx, and vagina with lymphadenopathy and a hemorrhagic spleen. Lesions may also appear in the trachea. Lesions in the lung are severe manifesting as lentil sized white pox nodules to a consolidating necrotizing pneumonia. Lesions occasionally reach the abomasum and are accompanied by a hemorrhagic enteritis.

22.2.10.7.1

DIFFERENTIAL DIAGNOSIS

- Contagious ecthyma (orf)
- Bluetongue.

22.2.10.8

TREATMENT

No specific treatment is advised, but palliative treatment may be necessary in severely affected animals.

22.2.10.9

CONTROL

Control in free countries or regions necessitates prohibition of importation from infected areas, and if the infection is introduced, ring vaccination, the destruction of affected flocks and the quarantine of infected premises should be instituted.

Vaccination with natural lymph has been practised in some affected areas, but is capable of spreading the disease. Natural infection with one capripox strain imparts immunity to all capripox infections and vaccination with a **single capripox vaccine** will give protection across all species and against all capripox infections.[2]

A large variety of commercial vaccines is now available, and there is no easy basis for comparison.[3] Killed virus vaccines elicit, at best, temporary protection but available live attenuated vaccines appear to give excellent protection for periods greater than 1 year.[2,3,17,18] Colostral antibody interferes with response to vaccination before 6 months of age. A subunit capripox virus vaccine has been developed.[19]

Vaccination in the face of outbreak is unlikely to prevent deaths during the subsequent 2 weeks and, if needle hygiene is poor, may facilitate the spread of the disease.

22.2.11 ## SWINEPOX

22.2.11.1 ### Synopsis

22.2.11.1.1 #### Etiology

Swinepox virus

22.2.11.1.2 #### Epidemiology

Widespread sporadic disease that is generally benign with low morbidity and low mortality in older pigs. High case fatality in congenitally infected and very young sucking piglets. Transmitted mechanically and by the hog louse

22.2.11.1.3 #### Clinical findings

Characteristic pox lesions mainly on skin of head, legs and belly

22.2.11.1.4 #### Clinical pathology

Demonstration of typical lesions by histology and virus by electron microscopy

22.2.11.1.5 Lesions

Typical pox lesions

22.2.11.1.6 Diagnostic confirmation

Demonstration of typical lesions by histology and virus by electron microscopy

22.2.11.1.7 Treatment

None

22.2.11.1.8 Control

Control of hog louse

22.2.11.2 ETIOLOGY

The cause is swinepox virus, the sole member of the *Suipoxvirus* genus of Chordopoxvirinae subfamily of Poxviridae.[1]

22.2.11.3 EPIDEMIOLOGY

22.2.11.3.1 Occurrence

Swine pox (pig pox) occurs worldwide where swine are raised and is more common in swine units where there is poor sanitation.

22.2.11.3.2 Methods of transmission

Transmission is by contact transmission and mechanically by the pig louse (*Haematopinus suis*), and possibly by flies and other insects.[2] Young sucking pigs may have lesions on the face, with similar lesions on the udder of the sow, with spread by direct contact. The virus can survive in scab material for several months.

22.2.11.3.3 Animal risk factors

The virus infects only swine and can infect all ages but clinical disease is most commonly seen in young piglets. It is usually a sporadic disease with occasional

outbreaks affecting a cluster of litters within a herd and of short duration. Some or all pigs in a litter may show clinical signs.[3] The disease may appear apparently spontaneously or may occur only in pigs brought into the contaminated environment of a herd in which the indigenous pigs are immune.

The incidence in individual herds may be high. Mortality is usually low except in very young piglets and congenitally affected piglets where mortality rates can be high.[2,3] Congenital infection presents with a low morbidity but high case fatality.[3–6] Older animals seem to suffer little ill effect.[2]

22.2.11.4

PATHOGENESIS

In field cases, the lesions progress through the classical phases of poxvirus infections but do not usually proceed past the pustular or vesicle stage. At this time there is rupture and the formation of scabs which heal and drop off. Congenital infection is believed to occur when naïve pregnant sows become infected and develop viremia with infection of the fetal membranes. Not all fetuses are born affected and compartmentalization of placentas may restrict further uterine spread as occurs with parvovirus infections.[3]

1431 1432

22.2.11.5

CLINICAL FINDINGS

Small 1 to 1.5 cm diameter papules develop first and may pass through the pustular and vesicular stage very quickly with the formation of red-brown, round scabs. In neonatal pigs, the rupture of many vesicles at one time may cause wetting and scab formation over the cheeks, and conjunctivitis and keratitis are present in many affected animals. In most cases the lesions are restricted to the belly and inside the upper limbs, but may involve the back and sides and sometimes spread to the face. Lesions may coalesce. A slight febrile reaction may occur in the early stages in young animals, and in sucking pigs deaths are observed. In adult pigs, detectable skin lesions are less well defined, restricted to the non haired softer skin areas and frequently do not progress through the developmental stages to form scabs. Congenital swinepox is characterized by striking lesions present in piglets at birth involving the skin and also commonly the tongue and hard palate.[3,4–6] Affected piglets were born from healthy sows. Affected piglets may be stillborn or die within a few days after birth.

22.2.11.6

CLINICAL PATHOLOGY

The diagnosis is confirmed by examination of skin biopsies.[2] Focal superficial erosions, marked epidermal hyperplasia with acanthosis, ballooning of epidermal cells, and occasional large eosinophilic intracellular inclusion bodies are present on histological examination.[2,4,5] Electron microscopy can be used to detect the viral particles and the virus can be cultivated in primary pig kidney cell tissue culture.[2,4,5]

22.2.11.6.1

DIFFERENTIAL DIAGNOSIS

The distribution of the pox-like lesions and the association of the disease with louse infestations suggest the diagnosis. Swinepox may resemble swine vesicular disease, which is characterized by vesicles on the coronary bands, lips, tongue, and snout.

Lesions associated with *Tyroglyphus* spp. mites are usually larger and occur anywhere on the body, and like those of sarcoptic mange, are usually accompanied by itching. The causative mites are detectable in skin scrapings. Ringworm and pityriasis rosea have characteristic lesions that do not itch, occur in older pig than typically does swine pox, and fungal spores are present in scrapings in the former disease.

A vesicular disease with necrosis resembling swine pox has been attributed to infection with parvoviris[7] but there is little evidence that parvovirus is a primary skin pathogen.[8]

22.2.11.7

TREATMENT

No specific treatment is available and lesions cause so little concern to the pig, and heal so rapidly, that none is attempted.

22.2.11.8

CONTROL

Vaccination is not usually practiced and control of the pig lice is the principal prophylactic measure attempted in most outbreaks.

22.2.12

HORSEPOX

Horsepox is a benign disease characterized by the development of typical pox lesions either on the limbs, or on the lips and buccal mucosa.[1] The causative ungulate **poxvirus** is identical to the virus of true cowpox and is transferable to cattle and to humans. Infection of a foal by **cowpox** was associated with streptococcal septicemia and death.[2] Horsepox is rare. It is a benign disease, but badly affected horses become debilitated and occasionally young animals may die. It is spread by contact with infected grooming tools, harness, and by handling. Immunity after an attack is solid.

Typical pox lesions develop in a '**leg form**', or in a '**buccal form**'. In the '**leg form**' nodules, vesicles, pustules, and scabs develop, in that order, on the back of the pastern and cause pain and lameness. There may be a slight systemic reaction with elevation of temperature. In the '**buccal form**' similar lesions appear first on the insides of the lips and spread over the entire buccal mucosa, sometimes to the pharynx and larynx and occasionally into the nostrils. In very severe cases, lesions may appear on the conjunctiva, the vulva, and sometimes over the entire body. The buccal lesions cause a painful stomatitis, with salivation and anorexia as prominent signs. Most cases recover with lesions healing in 2–4 weeks.

Cowpox was associated with severe ulcerative glossitis, stomatitis, esophagitis and gastritis in a foal.[2] Other lesions included polyarthritis and nephritis, though these later lesions could have been caused by streptococcal septicemia.

Differential diagnoses include greasy heel, vesicular stomatitis; viral papular dermatitis, molluscum contagiosum[3] and Uasin gishu. See Tables 22.3 and 22.4.

There is **no specific treatment**. Local wound care may hasten healing. Because of the contagious nature of the disease, rigid isolation and hygiene in the handling of infected horses is essential. No vaccine is available.

22.2.13

UASIN GISHU

This is a skin disease of horses of the Uasin gishu plateau of Kenya and neighboring areas associated with a pox virus.[1] Lesions on the head, neck, and flanks resemble papillomas.[2,3] The source of the virus, and its method of transmission, are unknown, although a wildlife host is presumed.[1] Various stages of the lesions can be present in the same horse, and lesions may develop and regress intermittently for years.[4] There is no specific treatment and no control methods are reported.

22.2.14

ULCERATIVE DERMATOSIS OF SHEEP

Ulcerative dermatosis of sheep is an infectious disease characterized by the destruction of epidermal and subcutaneous tissues, and the development of raw, granulating ulcers on the skin of the lips, nares, feet, legs, and external genital organs. The lesions on the **lips** occur between the **lip and the nostril**, those on the **feet** occur in the interdigital space and above the coronet, and the **genital lesions** occur on the glans and the external opening of the prepuce of rams, and the vulva of ewes.

A virus, very similar but antigenically different to the ecthyma virus, is the cause of the disease, which is likely to be confused with contagious ecthyma. However, the lesions are

ulcerative and destructive rather than proliferative as in ecthyma. It is not highly infectious like bluetongue or sheeppox, and the '**lip-and-leg**' distribution of the lesions differentiates it from balanoposthitis of wethers, strawberry foot rot, foot rot, and interdigital abscess. The presence of lesions on the glans penis, and their absence from mucosae, the typical ulcerative form of the lesion, the absence of pus and the susceptibility of recovered animals to infection with ecthyma virus are diagnostic features of ulcerative dermatosis.

Table 22.3 Differential diagnosis of diseases of horses characterized by discrete lesions of the skin only

	Epidemiology			
Disease	**Method of spread**	**Behavior in herd**	**Lesions**	**Clinical pathology**
Horsepox	Extremely rare, benign. Spread by contact, rugs, grooming tools	Solid immunity after attack. No recurrence. lesions heal 2–4 weeks	Typical pox lesions in mouth or behind pasterns. Rare cases have lesions in mouth, nostrils, vulva	Electron microscopy of swab from lesion ungulate poxvirus present
Vesicular stomatitis	Occurs horses, cattle, pigs. Spread by insert or contact. Clustered outbreaks summer and autumn	Lesions last only 3–4 days. Solid immunity for 6 months	On tongue and lips. Uncommon on udder or prepuce. Vesicles up to 2 cm rupture leaving raw area, profuse ropey saliva. Heal quickly	Virus isolation, PCR. Many serological tests available
Viral papular dermatitis	Insect vector. May affect many horses at one time. Local horses immune. Summer and autumn.	Recovered in 10 days to 6 weeks. Benign, disappears without trace	Generalized cutaneous papules 0.5–2 cm dia, dry crust at 7–10 days, then spot of alopecia	Virus in lesions culturable in eggs
Staphylococcal dermatitis	Sporadic. Lesions under harness suggest pressure or spread by contact. A common disease	No information, does not spread much. But very difficult to cure in individual. Horse will not work under harness	5-mm nodules then pustules. slough taking small scab and hair. Very painful to touch	*Staphylococcus aureus* culture from swab of lesion

Deep ringworm	Diffuse ringworm more common. Spread easily by direct contact or harness or tools	Sporadic usually. Difficult to cure	3-mm dia follicular nodule, hair loss leaving bald patch. No extensive lesions. Sore to touch, itchy. Spreads from axilla	*Trichophyton* or *Microsporum* spp. on swab
Demodectic mange	Spread via grooming tools and rugs. Rare	Slow spread	Lesions around face and eyes initially	*Demodex* spp. in scraping
Mycotic dermatitis	Wet humid weather predisposes. Prolonged wetness. Mud leads to foot lesions. Biting flies may spread other forms	May be number affected if weather conditions suitable	Lesions commence on head at muzzle, around eyes, lacrimination and mucopurulent nasal discharge, on lower legs – or generalized. Not itchy, may be sore. Matted hair and scab can be lifted off an ovoid, slightly bleeding area	Branching filamentous *Dermatophilus congolensis* on smear of lesion
Tyroglyphosis	In horses fed recently harvested, infested grain, or at pasture	Transient self-limiting disease	Dermatitis, itchy, scaly with rubbing get alopecia and scab formation on muzzle and face, lower limbs at flexures	Larvea of chigger mites *Prediculoides* and *Trombicula* spp. in scraping
Photosensitization	Rare in horses. Feeling on St John's wort or liver damage-producing plants, due to cholangitis	Occurs only in sunlight. Disappears on removal from damaging feed and sun	Extensive edema, weeping dermatitis or skin sloughing on white parts. May also be signs of hepatic insufficiency	Nil

Queensland itch	Sporadic. During insect season. Only in horses outdoors	Only hypersensitive horses affected. Disease persists as long as insects present. Interferes with work and grazing	Intensely itchy. Lesions at tail butt, along back, withers, crest, poll, ears, down sides. Papules, hair rubs off. Pachydermia, no weeping	Hypersensitivity indicated by eosinophillia in skin biopsy
Ringworm	Ready transmission by contact and with equipment and premises. Most serious in winter	Spontaneous recovery in about 3 months. Spread in herd can be very rapid	Thick, dry crumbly scab, 2–3 cm dia, or diffuse alopecia with scaliness begin at girth or under head stall	*Trichopyton* and *Microsporum* spp. on scraping
Note: See also cutaneous globidiosis, multiple abscess caused by Corynebacterium pseudotuberculosis, anhidrosis, congenital abscence of skin.				

A morbidity rate of 15–20% is usual, but up to 60% of a flock may be affected. Mortality is low if the sheep are in good condition and the lesions are treated. Physical contact at breeding time seems to be the most probable method of spread.

The lip cutaneous form of this disease is very **rare** and possibly has disappeared since its original description, or is very uncommon. A clinically similar disease to the genital infection of ulcerative dermatosis, with balanoposthitis and vulvovaginitis, is associated with *Mycoplasma mycoides*.[1]

22.2.15

Diseases associated with Chlamidiae

The Phylum Chlamidiae consists of obligate intracellular bacterial pathogens and contains four families of which two have members that are associated with agricultural animal disease. The family Chlamydiaceae and has recently been reclassified into two genera with C*hlamydophila abortus*, *Chlamydophila pecorum and Chlamydophila pneumoniae* and *Chlamydia suis* associated with animal disease. A different family within the Chlamidiae contains *Waddlia chondrophila* that has been isolated from aborted fetuses.

The prominent farm animal and horse diseases associated with Chlamydiaceae are chlamydial polyarthritis (*Cp. pecorum*) and chlamydial abortion (*Cp. abortus*) which are described below, and sporadic bovine encephalomyelitis (*Cp. pecorum*) which is described elsewhere under that heading. *Cp. pecorum* may also be an etiological agent in some outbreaks of ovine contagious ophthalmia which is described under that heading.

Table 22.4 Differential diagnosis of diseases of horses characterized by lesions of the skin of the lower limbs only

	Epidemiology			
Disease	**Method of spread**	**Behavior in herd**	**Lesions**	**Clinical pathology**
Glanders	Contact with infected horses. Ingestion from contaminated environment.	This is chronic form. Other cases of classical glanders with pulmonary and nasal mucosal involvement	Nodules and ulcers on nasal mucosa, purulent discharge. Stellate scars on septum. Limb lesions mostly at hock (medial aspect): nodules 1–2 cm, discharge honey-like pus	Mallein test. Complement fixation tests on serum. Transmission to guinea-pigs. *pseudomonas mallei* in smears
Epizootic lymphangitis (equine blastomycosis)	Occurs in out-breaks. Spread by spores on contaminated bedding. May survive in soil. Entry through skin abrasions	Horses cannot be worked. Common in large groups, e.g. military horses	Ulcers at hocks, lymph nodes at hocks swell and discharge creamy pus. Lymphangitis. Some cases generalized with pulmonary abscesses	*Histoplasma farciminosum* in smears of pus. Skin sensitivity test
Sporotrichosis	Slow spread. Sporadic cases. Spread by contact and contamination of environment	Lesions heal 3–4 weeks but new crops keep disease going	Painless nodules at fetlocks ulcerate then heal. Lymphangitis in some animals	*Sporotrichum schenkii* on smear

Swamp cancer (Pythiosis)	Sporadic. Infection or invasion of wound	Does not spread	On lower limbs, or ventral abdomen, or below medial canthus of eye, lips. Papules to plaques 1 cm thick, connective tissue with ulcers up to 20 cm, with inspissated pus in pockets	Biopsy and scrapings for hyphae of *Pythium insidiosum, Entomophthora coronata*, larvae of *Habronema megastoma*
Greasy heel	Sporadic cases only. Horses standing in manure and urine	Not contagious. But can be chronic and incapacitating	Horizontal cracks and fissures behind pastern, very lame. Much sebaceous exudate. May develop cellulitis	Nil
Ulcerative lymphangitis	Infection of skin wounds in dirty stable	Lesions heal 1–2 weeks. New lesions develop for up to 12 months	Painful nodules around pastern rupture, creamy green pus. Lame. Lymphangitis with ulcers	No lymph node involvement. *Corynebacterium pseudotuberculosis* in pus. Other organism can cause similar disease.
Chorioptic mange	Widespread. Mostly draft and other working horses	Most horses in group affected	Violent stamping, rubs back of pasterns, swollen, scabby, cracked, greasy, painful to touch; lame	Scrapings reveal mites *Chorioptes equi*
Note: See also horsepox (Table 22.3).				

Other infections and possible diseases associated with these agents and with *C. suis* and *C. pneumoniae* are less commonly reported although it is possible that they underdiagnosed.[1]

The standard method of diagnosis of chlamydial disease is by isolation in embryonated eggs or in cell culture. However, some strains are difficult to grow and require specialist facilities and expertise. Also the complement fixation test, which is the standard serological test for chlamydial disease, lacks sensitivity and specificity because of cross reaction between chlamydial species.[1] The organisms are obligate intracellular pathogens and depend on the host cell for energy in the form of adenosine triphosphate (ATP). Outside of the host cell

they exist as metabolically inactive elementary bodies, which have a rigid cell wall and are unable to grow or divide. The elementary bodies attach to host cells and are taken in by phagocytosis. Inside the phagosome they become the metabolically active reticulate body (initial bodies), which have flexible cell walls and grow and divide to form an intravacuolar microcolony called a chlamydial inclusion. Nascent elementary bodies are formed, the host cell is lysed, and the elementary bodies are released with the cycle being accomplished in 36 to 96 hours, depending on species. The current development of new and more sensitive and specific molecular and serological tests such as PCR and the use of recombinant major outer membrane proteins as antigens can allow species specific laboratory diagnosis and should allow a better definition of the importance of *C. pecorum* and *C. pneumoniae* and *C. suis* to agricultural animal disease.[1,2]

22.2.15.1

REPRODUCTIVE DISEASE

In addition to enzootic abortion in ewes Chlamydiaceae have been associated with reproductive inefficiency in swine and cattle.

In **swine**, infection with *Cp. pecorum* and *Cp. abortus* have been associated with increased rates of returns to estrus, abortion, mummification, stillbirth and increased perinatal and neonatal mortality. Some studies of swine in herds with and without a problem of early embryonic death have found no significant difference in the seroprevalence of antibodies to Chlamydiaceae but have found a significant difference in the presence and proportion of *Cp. abortus* in cervical swabs and in the uterus and oviducts at slaughter. A dual infection with *C. suis* was also demonstrated in some cervical swabs in these studies but, whereas an association of *Cp. abortus* and reproductive inefficiency was evident, the contribution of *C. suis* to reproductive inefficiency was less clear.[3–5]

Reports of reproductive inefficiency in swine are largely from Germany and Switzerland, but in large industrial piggeries in eastern European countries, in addition to being implicated in severe outbreaks of abortion and production of weak piglets, infections with Chlamydiaceae are reported to produce reproductive disease in boars, polyarthritis and polyserositis in young pigs, arthritis in finishing pigs, and pneumonia and conjunctivitis.[6] In contrast other studies suggest that chlamydial infections are endemic in pigs and that the significance of Chlamydiaceae as pathogens in swine remains to be determined.[7]

1434 1435

In **cattle,** *Cp. abortus* is a cause of bovine abortion but much less commonly than in small ruminants and not causing enzootic disease. Infertility and **endometritis** in cattle has been

associated with the organism and has been reproduced experimentally.[8] However, there is debate as to the importance of Chlamydiaceae as major reproductive pathogens in cattle as non-clinical infection of the reproductive tract is common. A recent study using PCR found a high (53%) prevalence of *Cp. abortus* and **Cp. pecorum** infection in the vagina of virgin heifers.[9] A subsequent study established that infection occurred in calves at a very young age. In this study *Cp. pecorum* infection was fivefold more prevalent than *Cp. abortus* infection and was most frequently detected by vaginal swabs compared to rectal or nasal swabs.[10]

Waddlia chondrophila was initially isolated from an aborted calf in the USA and has subsequently been demonstrated in aborted fetuses in other countries. Serological studies suggest that it might have a role in the causation of bovine abortion. Free living amoeba may serve as hosts.[11–13]

22.2.15.2

OTHER DISEASE ASSOCIATIONS

C. suis has been associated with enteric disease in pigs but is also present in the intestines of clinically normal finishing and adult pigs.[3,14]

C. suis has also been associated with respiratory disease in swine and this has been reproduced experimentally in conventional pigs by aerogeneous challenge.[15]

Cp. psittaci has also been demonstrated in domestic and wild pigs (*Sus scrofa*).[16,17] Other miscellaneous occurrences are cases of **pneumonia** in most animal species, including horses,[18] cattle, sheep, goats and pigs, and **orchitis** and **epididymitis** in male ruminants and intestinal infections in ruminants and pigs.[19,20] It is not possible to classify the Chlamydiae associated with some of these reports. The horse respiratory isolate is closely related to human isolates of *Cp. pneumoniae*.[21] Enteritis and diarrhea in calves, from which *Cp. pecorum* can be isolated, are usually mixed infections and the pathogenicity of the chlamydiophila as a cause of enteritis is open to doubt.

22.2.16

CHLAMYDIAL POLYARTHRITIS

Virulent chlamydia, including *Chlamydophila pecorum*, can be isolated from the joints of calves, lambs, and foals clinically affected by polyarthritis. The experimental disease in calves begins as a chlamydemia, followed by localization in the joints. In calves, the disease is uncommon but often fatal. In lambs, it is a common disease in sheep feedlots in the United States, but the mortality rate is low.[1] The strain associated with arthritis is not common in the

United Kingdom[2] and polyarthritis in the UK has been associated with a chlamydial strain distinct from *Cp. pecorum*.[3]

In pastured sheep, the morbidity may be as high as 80% but deaths are usually less than 1%. In calves, the disease is more commonly sporadic but response to treatment is poor and affected calve are often destroyed on humane grounds. Intestinal infection with *Chlamydophila pecorum* is common in pastured lambs between 3 and 9 months of age, but is not associated with clinical disease.[4]

The clinical signs in calves and lambs include gross swelling of most limb joints but especially the larger joints, lameness, stiffness, unwillingness to move, recumbency, depression, conjunctivitis, and fever of 39–42°C (102–108°F). The navel is unaffected but there may be signs caused by localization of the infection in other organs, e.g. pneumonia, encephalomyelitis, and renal abscess. Clinically, the disease is indistinguishable from polyarthritis caused by other infections such as *Mycoplasma* and *Haemophilus* spp.

22.2.17 CHLAMYDOPHILA ABORTION (ENZOOTIC ABORTION OF EWES, OVINE ENZOOTIC ABORTION)

22.2.17.1 Synopsis

22.2.17.1.1 Etiology

Chlamydophila abortus

22.2.17.1.2

Epidemiology

Prevalence varies with country. Major source of infection is the placenta and uterine discharge of aborting ewes, and infection is by the oral route. Pregnant sheep infected by contact with aborting ewes usually do not abort until the next lambing season. Zoonotic

22.2.17.1.3

Clinical findings

Abortion, stillborn and weak-born lambs

22.2.17.1.4

Necropsy findings

Necrotic and hemorrhagic placental cotyledons, intercotyledonary areas thickened, edematous and leathery

22.2.17.1.5

Diagnostic confirmation

Demonstration of the organism in the placenta and a rising titer in paired serum samples

22.2.17.1.6

Control

Isolation of aborting ewes. Killed adjuvanated vaccine gives short-term protection. Live attenuated vaccines

22.2.17.2

ETIOLOGY

Chlamydophila abortus (previously *Chlamydia psittaci* bioype1/serotype1) has a tropism for ruminant placenta and causes the disease commonly referred to as ovine enzootic abortion (OEA). The organism causes a similar disease in goats, and while this organism also can produce abortion in cattle, pigs and horses, abortion associated with this organism is not common in these species.

There is considerable genetic diversity amongst strains that cause abortion.[1,2]

22.2.17.3 EPIDEMIOLOGY

22.2.17.3.1 Occurrence

The disease is one of the commonest causes of diagnosed abortion in sheep and goats in the United Kingdom, the United States,[3] and in other countries. In the UK it accounts for approximately 45% of abortions, and it is particularly common in lowland flocks that are intensively managed at lambing time. However, its importance varies from country to country. It is an uncommon cause of abortion in Northern Ireland,[4] and the disease does not occur in Norway or New Zealand.[5]

1435 1436

There have been several studies of seroprevalence in Europe which show a high seroprevalence in both domestic and wild ruminants but, until recently, most surveys have used the complement fixation test which is not specific for *Cp. abortus* and the seroprevalence rates for *Cp. abortus* in different countries are not well established.[6]

22.2.17.3.2 Source of infection and transmission

Infection is introduced into a flock by the purchase of latently infected replacements which usually abort at the end of their first pregnancy.

Within a flock, the **major source of infection** is the placenta and the uterine discharge of aborting ewes. The main routes of transmission of *Cp. abortus* are through ingestion of organisms shed in vaginal fluids and placental membranes at the time of abortion or lambing, or through inhalation of aerosols from the environment.[7] Pasture and the environment are contaminated by vaginal discharges, placenta and aborted fetuses, and infected ewes shed the organism for a week before aborting and for 2 weeks afterwards. The elementary body of *Cp. abortus* is resistant to both physical and chemical influences as it is metabolically inactive and the rigid cell envelope is osmotically stable and poorly permeable. As a consequence the organism is believed to survive for several days on pasture and longer in cold weather.

Infection of the ewe lamb may occur at birth, shortly following, or at subsequent lambing periods. Infection of pregnant ewes in early or mid gestation results in either abortion in the final 2–3 weeks of gestation, or the birth of stillborn or weak lambs that frequently die in the first few days of their life. Abortion always appears in the last weeks of gestation regardless of the time of infection. Infection of ewes in the last 5–6

weeks of pregnancy usually leads to the development of a latent infection, where ewes appear to be uninfected until the next lambing season, when they abort. Thus, late pregnant sheep may be infected by contact with aborting ewes but usually do not themselves abort until the next lambing season.

The common pattern of infection and disease is the a small number of abortions in year 1 usually resulting from the introduction of infected replacement ewes, followed by an epidemic abortion storm where up to 35% of ewes abort in the last 3 weeks of gestation or give premature birth to weak or dead lambs. After abortion, the ewes develop a protective immunity and, in endemically infected flocks, 5–10% of the ewes abort annually. Surviving lambs born to infected mothers may be affected by EAE in their first pregnancy.[8–10]

Sheep that have aborted, subsequently re-breed successfully, do not have further abortions, and the organism is not present in the placenta or vaginal discharge of subsequent pregnancies. However, levels of immunity vary and some may excrete organisms at estrus or seasonally for up to 3 years.[11]

In chronically infected sheep, **persistent infection** can be demonstrated in the endometrial cells of the reproductive tract,[12] and the organism is excreted in vaginal fluids during **estral periods**.

Vaginal challenge of ewes at breeding time will result in infection and subsequent abortion, and venereal or passive venereal transmission is a possible route of infection,[13,14] but it does not appear to be a common or important route. Chronic infection of the male genital tissues has been recorded and infection may impair fertility in both rams and bulls.[8]

The epidemiology of abortion with this agent in cattle is unknown but it may transmit to cattle from infected sheep on the same farm.[2,15]

22.2.17.3.3

Experimental reproduction

The disease is readily reproduced experimentally.[16,17] Following subcutaneous injection there are no signs of clinical disease other than a modest increase in rectal temperature for two days after infection. There is a systemic antibody response that peaks 2 weeks after infection and then decreases until just before abortion or parturition, when there is a second increase in the antibody levels to *Cp. abortus*. Experimental infection at 70 to 75

days pregnancy can result in abortion in the last 2 to 3 weeks of pregnancy or the birth of stillborn or live lambs. There is variation in the severity of the placental lesions in experimental infections. Abortion is associated with severe placental lesions but the reason for the variation in severity and fetal manifestations is not known.[17]

22.2.17.3.4

Economic importance

Enzootic abortion is the most common infectious cause of abortion in lowland flocks that are intensively managed at lambing time, and has a major economic impact on agricultural industries worldwide. There are no recent estimates of economic impact but losses in the UK were estimated in the early 1990s at £15–20 million per annum.[10]

22.2.17.3.5

Zoonotic implications

There is some risk for shepherds, and those in allied fields such as abattoir workers, to contract respiratory infection with this organism but the major zoonotic risk is to pregnant women because of the ability of *Cp. abortus* to colonize the human placenta. Human infection in early pregnancy results in abortion whereas later infection can result in stillbirth or pre-term labor.[8,18] Infection is believed by the oral route from infected hands or food following direct handling of infected sheep or goats or infected clothing. Practices at lambing such as mouth to mouth resuscitation of weak lambs or bringing weak lambs into the house to be warmed promote zoonotic spread. Infected placentas and dead lambs should be handled using gloved hands and disposed of by burning or burial.

The organism can be detected in milk both in sheep and in cattle and raw milk could also pose a risk for zoonotic infection.[19,20]

22.2.17.4

PATHOGENESIS

Following infection, it is thought that the organism resides first in the tonsil, and is then disseminated by blood and lymph to other organs although the site of latent infection is not known. The latent state is maintained under the control of the proinflammatory cytokine interferon-gamma (IFN-γ).[21] Release from the latent state during pregnancy is believed due to immune modulation and leads to bacteremia and infection of the placenta.[8,10]

The organisms invade the trophoblast cells of the fetal cotyledon following which infection spreads to the intercotyledonary regions of the chorion to produce a suppurative necrotic

placentitis with impairment of the maternal–fetal exchange of nutrients and oxygen and fetal death and abortion. An inflammatory response in the fetus may also contribute to fetal death.[16,17]

It is not known why, regardless of the time of infection, pathological changes in the placenta do not commence before 90 days gestation[17] or even as late as 120 days.[16]

22.2.17.5

CLINICAL FINDINGS

There are generally no premonitory indications of the impending abortions Abortion occurs in late pregnancy; ewes appear to suffer no systemic effects, but retained placenta and metritis can be sequel in goats. Additional losses are caused by stillbirths and weak-born lambs and kids which die soon after birth.

A vaginal discharge lasting up to 3 weeks following the abortion is common.

1436

1437

In **cattle**, the infection causes abortion in the last third of pregnancy. Infected calves born alive may show lethargy, depression, and may be stunted.

22.2.17.6

CLINICAL PATHOLOGY

Infection in aborting animals can be demonstrated serologically by rising titers in paired serum samples and by culture of the organism.[15]

The **complement fixation test** is commonly used to identify flocks free of infection. It has moderately good sensitivity but is not specific for the agent of due to a common antigen shared by all members of the family and also to some Gram-negative bacteria.[22] For samples testing positive, a Western blot examining for antibody against specific antigens can be used as a reference test in flock accreditation.[23] **ELISA tests**, based on whole cell chlamydial elementary bodies or extracts of them, have better specificity than the complement fixation test but poorer sensitivity. A comparison of tests in common use in the United Kingdom in the mid 1990s found that none were both highly sensitive and specific.[23] ELISA tests that are based on segments of the membrane outer protein or synthetic peptide antigens have greater sensitivity and specificity and are now used in diagnostic, epidemiologic and seroprevalence studies.[7,22,24,25]

22.2.17.7

NECROPSY FINDINGS

Aborted fetuses typically have no gross abnormalities. Fetal fluid may contain chlamydophilal antibody and although less sensitive than either isolation in McCoy cells or detection of chlamydial LPS antigen, can be of particular use when placenta is not available. Histologically, there may be mononuclear cell infiltration of hepatic portal areas and multifocal areas of hepatitis. In both cattle and sheep, the placenta is critical for diagnosis of the condition. Placental cotyledons are necrotic and hemorrhagic, and the **intercotyledonary areas** are thickened, edematous, and leathery. This is in direct contrast to the targeting of cotyledons seen with toxoplasmosis. The *Chlamydophila* organisms can be observed in tightly-packed sheets within the cytoplasm of swollen trophoblasts in formalin-fixed tissue samples, or in direct placental smears via modified Gimenez, Koster's, or other appropriate staining methods. Well-preserved, fresh placenta should be examined as the organisms are difficult to demonstrate in the fetus. Immunohistochemical stains perform well on formalin-fixed specimens. Most laboratories are reluctant to culture *Chlamydophila* spp. due to the zoonotic potential of these agents.

22.2.17.7.1

Samples for confirmation of diagnosis

- **Bacteriology** – chilled liver, lung, placenta (CYTO, PCR, ELISA)
- **Histology** – fixed placenta, liver (LM, IHC)

Note the zoonotic potential of this organism when handling carcasses or submitting specimens.

22.2.17.7.1.1

DIFFERENTIAL DIAGNOSIS

Other causes of abortion in cattle and ewes are given in (Tables 18.7 and 18.8).

22.2.17.8

CONTROL

Ewes that have aborted should be **isolated** from the rest of the flock. There should be proper hygiene of the lambing areas and in the disposal of aborted materials. Tetracycline has been used in early pregnant sheep within an aborting flock to attempt to reduce subsequent abortions but the efficacy is questionable.

22.2.17.8.1

Vaccines

Two types of vaccine are currently available but there is yet no vaccine that has excellent efficiency against this disease.

Killed vaccines, composed of egg-grown or tissue culture grown organisms of one or two strains have been used for several decades. They are variably effective and can reduce the frequency of abortion and the shedding of the organism. However, outbreaks have occurred in vaccinated sheep and strain variation is a possible cause of failure of monovalent vaccines.[1]

The addition of Freund's incomplete **adjuvant** has provided a vaccine that provides better protection[26] and it has been recently claimed that specific adjuvants can markedly improve the efficiency of killed vaccines against naturally occurring enzootic abortion.[27,28]

A **live vaccine** containing a temperature-sensitive attenuated strain of *C. psittaci* has shown to engender excellent, but not complete, protection against challenge; with five different abortigenic strains of *Cp. abortus* there was a marked reduction in the number of ewes aborting and marked increase in live-born lambs compared to controls.[29] It is labeled for sheep but not for goats. Concern has been expressed for the zoonotic potential of an attenuated vaccine.[27]

Recombinant and DNA vaccines have shown disappointing protection in studies with experimental challenge.[30,31]

23 Chapter 23 Diseases associated with prions

23.1 INTRODUCTION

The transmissible spongiform encephalopathies (TSEs) are a group of progressive neurological disorders that are transmissible and affect a number of animal species and humans (Table 23.1). They are non-febrile with long incubation periods and a long course of disease.

There is debate of the nature of the infective agent causing TSEs. An abnormal folded isoform, designated PrP^{Sc}, of a host encoded cell-surface glycoprotein (prion protein, PrPc) accumulates during disease and is associated closely with infectivity. The function of PrP^{C} is not known and the mechanism whereby PrP^{C} is converted to PrP^{Sc} is uncertain. PrP^{Sc} is rich in β sheets and can be isolated as insoluble aggregates. A theory is that the transmissible agent is the abnormal isoform of the prion protein and that, in the infected host, this can recruit further alternatively folded prion protein. With this theory the long incubation period of prion diseases reflects the rise in level and deposition of PrP^{Sc} in a variety of tissues, including brain, eventually resulting in fatal spongiform encephalopathy.

Scrapie affects sheep and goats and is the prototypic disease for the group.

Although scrapie in sheep has been recognized for over 200 years the recent epidemic of bovine spongiform encephalopathy has focused public attention and scientific research on the TSEs. With scrapie, and other TSEs, transmission can be effected by crude or purified extracts of brain or other tissues from affected animals, and the infective agent is very resistant to ionizing and ultraviolet irradiation and to reagents that damage or modify nucleic acids. This, along with other experimental findings, has led to proposals that the infectious agent in scrapie, and other TSEs, is the PrP^{Sc} itself, and not a small, unconventional virus or virino as previously proposed. The structure of the infecting PrP^{Sc} is believed to imprint upon the normal cellular precursor PrP^{c}, resulting in a change to the abnormal isoform which is protease-resistant and accumulates in cells.

Table 23.1 Transmissible spongiform encephalopathies in animals and humans

Disease	Acronym	Species	Etiology	First described
Creutzfeldt–Jakob disease	CJD	Man	Sporadic Familial Iatrogenic	1920
Gerstmann–Straussler–Scheinker disease	GSS	Man	Familial	1936
Kuru		Man	Acquired	1957
Fatal familial insomnia	FFI	Man	Familial	1992
Variant Creutzfeldt–Jakob disease	$_{V}$CJD	Man	Acquired	1996
Scrapie		Sheep, goats, moufflon	Natural	1738
Transmissible mink encephalopathy	TME	Mink	Acquired	1964
Chronic wasting disease	CWD	Deer, elk	Natural	1980
Bovine spongiform encephalopathy	BSE	Cattle	Acquired	1986
Zoo ungulate TSE		Nyala, kudu, gemsbok, oryx	Acquired	1986
Feline spongiform encephalopathy	FSE	Zoo cats (puma, cheetah and domestic cats)	Acquired	1990

Naturally occurring TSEs, such as sporadic CJD in humans or transmissible mink encephalopathy in mink, are associated with individual species or with closely related species as with scrapie in sheep, goats and mouflon (*Ovis musinum*) and chronic wasting disease in mule deer (*Odocoileus hemionus*), white-tailed deer (*Odocoileus virginianus*) and elk (*Cervus elaphus nelsoni*).

The results of attempts at inter-species transmission of these diseases are variable. While, by definition, each TSE is transmissible, the species to which they will transmit varies between the TSE, and can be influenced by the route of challenge, and the tissues that contain infection also varies according to the particular TSE. Frequently they do not transmit. Successful primary transmission between different mammalian species typically requires larger dose to

effect disease than would be required for transmission to the same species. Also, usually, parenteral or intracerebral routes are required and success is greater with young animal recipients. This is the so-called 'species barrier', which may be absolute or partial in that it will affect only a proportion of animals on first passage, or may result in an extended incubation period on first passage.

When using transmission studies to detect the presence of one of these agents optimal sensitivity is with a recipient host the same species. Transgenic mice may eliminate this barrier.

The 'gold-standard' technique for the diagnosis of TSE agents is the passage of tissue in panels of inbred mice, a technique known as 'strain typing'. Until recently this was the only way to differentiate scrapie and BSE. BSE presents with a characteristic incubation period, pattern of distribution and relative severity of the changes in the brain of the different mouse strains – the lesion profile – which is distinct from all scrapie strains tested to date.

When examining TSEs as a group, one cannot extrapolate the transmission particulars of one TSE to another nor can one extrapolate risk factors or epidemiology from one to another and certainly generalizations from an experimental model to a natural disease across a species barrier is scientifically inappropriate.

The literature on this subject is large. This chapter will discuss scrapie in sheep and goats, and bovine spongiform encephalopathy, which are the two TSEs of agricultural animals. It will also discuss the risk for BSE in sheep, particularly as this is a current cause for concern. Chronic wasting disease in deer is briefly described but has not shown any evidence for transmission to agricultural animals other than deer.

23.2 # SCRAPIE

23.2.1 ## Synopsis

23.2.1.1 ### Etiology

A transmissible agent that is highly resistant to chemical and physical agents, and appears not to contain DNA. Proposed to be due to a prion, a proteinaceous infectious particle. Susceptibility of sheep determined by genetics

23.2.1.2 ### Epidemiology

Transmitted primarily by contact with infected sheep and from environmental contamination; very long incubation period

23.2.1.3 ### Clinical findings

Non-febrile disease of adult sheep and goats with insidious onset and long clinical course. Affected animals show behavioral change, tremor, pruritus and locomotor disorder, and wasting

23.2.1.4 ### Clinical pathology

Demonstration of scrapie prion protein by immunostaining of lymphoid tissue

23.2.1.5 ### Lesions

Vacuolation of gray matter neuropil and neuronal perikarya, neuronal degeneration, gliosis

23.2.1.6 ### Diagnostic confirmation

Demonstration of scrapie prion protein

23.2.1.7 ### Treatment

None

23.2.1.8

Control

Slaughter eradication. Genetic testing and selection/culling. Selection/culling based on detection of scrapie prion protein in lymphoid tissue

Scrapie is a non-febrile, fatal, chronic disease of adult sheep and goats, characterized clinically by pruritus and abnormalities of gait, and by a very long incubation period. It is the prototypic disease for a group of diseases known as **transmissible spongiform encephalopathies**. This group also includes chronic wasting disease of deer and elk, transmissible mink encephalopathy, and feline spongiform encephalopathy, Creutzfeldt–Jakob disease and other spongiform encephalopathies of humans, and the relatively new disease, bovine spongiform encephalopathy, which is described separately under that heading. In Iceland scrapie is known as **rida**, in France as **La tremblante** and in Germany as **Traberkrankheit**.

23.2.2

Etiology

There has been a significant historical debate over the etiology of this disease, centered on whether the disease is inherited or associated with an infectious agent, and centered also on the nature of the infectious agent. Currently, it is believed that scrapie is associated with an infectious agent, but that the incubation period for clinical manifestation of the disease and the susceptibility of the host is determined by genetics.

Scrapie can be transmitted experimentally to other sheep and to certain laboratory animals, and infection induces the production in the brain, and some other tissues, of amyloid fibrils called scrapie-associated fibrils or prion rods. The main constituent of these is a disease-specific, protease-resistant neuronal membrane glycoprotein termed the **prion protein**, or PrP^{Sc}. PrP^{Sc} is an abnormal isoform of a host-coded membrane glycoprotein, PrP^{C}, and the transmissible spongiform encephalopathies are characterized by the accumulation of PrP^{Sc} in neuronal and other tissue.

Transmission can be effected by crude or purified extracts of brain or other tissues from affected sheep, and the infective agent is very resistant to ionizing and ultraviolet irradiation and to reagents that damage or modify nucleic acids. This, along with other experimental findings, has led to proposals that the infectious agent in scrapie is PrP^{Sc} itself, and not a small, unconventional virus or virino as previously proposed. The structure of the infecting PrP^{Sc} is believed to imprint upon the normal cellular precursor PrP^{C}, resulting in a change to

the abnormal isoform which is protease-resistant and accumulates in cells. The experimental studies and the arguments for this are reviewed elsewhere.[1–5]

More than 20 different strains of scrapie have been identified based on:

- Strain typing by differences in incubation time of the experimental disease in inbred strains of mice of different genotype
- The type, pattern, severity, and distribution of lesions in the brain of the different strains of experimental animals (lesion profiles)
- Resistance to thermal inactivation
- The type of disease produced in sheep and experimental animals (e.g. drowsy versus pruritic manifestations in goats)
- The ability of a strain to produce disease in different species of experimental animals.[3,6]

It is proposed that strain differences reflect differences in replicating information carried within the conformational state of the PrP^{Sc}.[2]

Co-infection can occur with scrapie. It is common for more than one strain to infect sheep but since one will have a shorter incubation period, it will predominate and be expressed first. The masked strains can be revealed by passage in different mice strains.[6,7]

23.2.2.1 ## EPIDEMIOLOGY

23.2.2.1.1 ### Occurrence

23.2.2.1.1.1 #### Geographic occurrence and incidence

Scrapie in sheep occurs enzootically in the United Kingdom, Europe, and North America. Outbreaks have been reported in Australia, New Zealand, India, the Middle East, Japan, and Scandinavia, principally in sheep imported from enzootic areas.[8,9] Australia and New Zealand used vigorous importation, quarantine, and culling policies to prevent subsequent entry of the disease and are considered free of disease.[8]

The true prevalence of the disease both within and between countries is not known as there has been no test to detect the presence of infection in individual sheep or in

flocks at all stages of infection. This is further confounded by secrecy about its existence in many flocks and breeds. This secrecy results from a fear of economic penalties that could result from the admission of infection.

In Great Britain, where the disease is enzootic and has been recognized for over 250 years, the true incidence is unknown, although a questionnaire survey in 1988 suggests that one-third of sheep flocks are infected.[9] In infected flocks the annual incidence ranges from 0.4 to 10 cases/100 sheep per year, with a mean of 1.1 cases/100 sheep per year.[9] However, the annual incidence can approach 20% of the adult flock 10), on occasions up to 40%, and in flocks where there is no selection against the disease the annual incidence and mortality can reach a level that results in disbandment of the flock or its non-survival.[11]

However, there is a difficulty in determining the occurrence of scrapie with any accuracy. In Britain, subsequent to the survey mentioned above, a large surveyin 1998 found 15% of flocks reporting a case of scrapie sometime in the past, with 2.7 reporting a case in the past year.[12,13] The authors of this survey, and of a subsequent follow-up survey which gave even lower numbers of flocks infected,[14] believe that the disease is grossly underreported, despite the fact that scrapie has been notifiable in Britain since 1993.

1440

1441

Farmer-consultation with a veterinarian about a case of scrapie and farmer-reporting of cases of scrapie is notoriously low. Historically, this has been due to factors such as the stigma associated with having scrapie diagnosed in a purebred flock and concerns for future sales or, in the case of commercial flocks, a lack of incentive to consult and a lack of concern since nothing can be done to cure the present case or prevent future cases. In England, it has been estimated that only 13% of farmers who had a suspect case of scrapie in the past 12 months reported it.[13] Possibly, the chance of improvement through genetic selection will alter this farmer trait.

The limitation of postal survey responses and their reliance on the recognition and diagnosis of scrapie by the farmer, coupled with the farmers reluctance to notify scrapie has prompted targeted surveillance using fallen stock and abattoir surveys throughout Europe. For most European countries, this targets a random sample of 6000 fallen sheep and 60000 routinely slaughtered adult native sheep and uses the cattle-validated rapid tests.[15]

The determination of the spatial occurrence of scrapie at the holding (farm) level is important in view of current thrusts at control and eradication. Surveillance of fallen stock is relatively efficient but has a low capture rate for infected holdings and abattoir surveys also show a lack of sensitivity.[15]

It has been observed that scrapie-affected flocks show a **scrapie signature,** in which older sheep with genotypes at greater risk for scrapie are under-represented,[7,16] and it has been proposed that this signature could be a way of identifying infected flocks. This observation has not been validated by other studies[17] and, for a scrapie signature to operate, it would require loss from scrapie to outweigh all other causes of attrition of older ewes in a flock and a relatively constant ram-allele input. The latter would be unlikely given ram turn over and variation in ram working lifespans.[17]

In the United States, the disease is believed to have been introduced in 1947, and between 1947 and 1992 was found in 657 flocks in 39 states.[18,19]

23.2.2.1.1.2

Host occurrence

23.2.2.1.1.2.1

Age

Scrapie is a disease of **mature sheep** although most are exposed as young sheep and the incidence decreases with age at exposure. The age-specific incidence in **sheep** is highest between 2.5 and 4.5 years of age and cases rarely occur under 18 months of age.[11] Natural disease in **goats** is rare. The age at death is similar to that in sheep, with a range from 2 to 7 years. The **case fatality rate**, with time, is 100%. The death loss is added to by the slaughter of infected and in-contact animals in countries where control and eradication is a practice.

23.2.2.1.1.2.2

Breed

Scrapie occurs in both sexes and in the majority of breeds, although the incidence is higher in some breeds than others.[12] Breed differences in prevalence occur in several countries; an example would be the high prevalence in the Suffolk breed in the United States relative to white-faced breeds and in some Hill breeds in the UK. These probably reflect breed and flock differences in genetic susceptibility to the development of clinical disease. Similarly, the occurrence of outbreaks of scrapie

may result from the introduction of infection to a genetically susceptible flock or to a change in the genetic structure of flocks that are infected.[20,21]

23.2.2.1.2

Methods of transmission

Knowledge of transmission of scrapie is based primarily on the experimental disease and observations of the natural disease in experimental flocks and has been reviewed.[10]

23.2.2.1.2.1

Sources and routes of infection

The usual method of introduction into unaffected flocks is by the purchase of pre-clinically infected sheep. Infectivity can be demonstrated in the placenta and fetal fluids of naturally occurring cases, but has not been demonstrated in the saliva, colostrum, milk, urine or feces of natural cases, even though it can be demonstrated in the intestine and nasal mucous membrane.[10,22] Ingestion of infected material appears the most likely route of infection, but scarification of the skin and conjunctival inoculation will also allow infection. Hay mites have been found to harbor the agent on scrapie infected properties and have been proposed as a reservoir for infection.[23]

23.2.2.1.2.2

Horizontal transmission

This is the usual method of spread and the placenta is considered the major source of infection for the mother to her lamb, and to other lambs in close contact. Under natural conditions the disease in flocks often runs in families, and whether or not a lamb contracts scrapie appears to depend primarily on the current or future scrapie status of its dam. It is common for all the VQR/VQR lambs from dams dying of scrapie to themselves develop scrapie.

Scrapie can also transmit between sheep in close contact and this can occur from sheep in the preclinical phase of the disease.[10,24]

Under natural conditions, scrapie occurs in sheep and occasionally spontaneously in goats. Under experimental conditions, scrapie has been observed to spread from sheep to goats by contact, and the little evidence available on the natural disease in goats is consistent with the view that the scrapie can be maintained by contagion in a herd of goats living apart from infected sheep.[25,26]

23.2.2.1.2.3

Vertical transmission

There is a greater risk for scrapie in lambs born to infected dams but this most probably reflects horizontal transmission at birth from placentas. There are conflicting results between studies that have examined transmission by embryo transfer, and the importance of vertical transmission to the epidemiology of the natural disease remains to be determined. However, epidemiological studies suggest that it is of rare occurrence and there is significant evidence against the occurrence of in-utero transmission.[10,20,27] The agent has not been demonstrated in the testes or semen of rams.

23.2.2.1.2.4

Environment

An infected environment can also be the source, and scrapie-free sheep can develop disease after grazing pasture previously grazed by scrapie-infected sheep, with infection by ingestion or possibly via abrasive lesions. Environmental infection can occur from the products of parturition and, although the scrapie agent has not been demonstrated in feces, it is suspected as being so in infected animals. The duration of infectivity on inanimate materials such as pasture has not been defined, but field and experimental observations[5] indicate that it is a long time, probably in excess of 3 years. A paired case-control study of risk factors in 61 scrapie affected flocks in Ireland found increased odds of scrapie occurring in flocks associated with the spreading sheep compost on the pasture and disposing of the placenta in the compost.[28]

23.2.2.1.2.5

Iatrogenic transmission

An outbreak of scrapie occurred in the 1930s following the use of a vaccine against louping ill prepared from the brains of sheep. More recently, the use of a vaccine against contagious agalactia has been epidemiologically linked to an outbreak of scrapie in sheep and goats in Italy where there was a high attack rate and high mortality affecting several birth cohorts.[29]

23.2.2.1.3

Genetics

Scrapie is recorded in most breeds of sheep but there are breed, family, and individual differences in susceptibility. There is substantial genetic control of the incidence of 1441 1442

disease, and in both the natural and experimental disease, genetics is a major determinant of susceptibility with the susceptibility of sheep strongly linked to certain polymorphisms in the sheep PrP gene.[27,30]

In earlier studies, experimental challenge and breeding showed that sheep could exhibit a long or short incubation period following challenge and that this difference in incubation period or susceptibility was determined by a single gene called *Sip* (scrapie incubation period). There is a similar gene in mice (*Sinc*) that determines incubation period and susceptibility following experimental challenge. The *Sip* gene has two alleles, *sA* and *pA*, which respectively shorten or prolong the experimental incubation period for most strains of the scrapie agent. The subsequent recognition of prion protein (PrP) and its association with scrapie led to the recognition of the gene that encodes PrP which was found congruent to *Sip* in sheep and *Sip* genetics have been entirely superseded by PrP genetics.[27]

Sheep have one pair of genes that influence susceptibility to scrapie known as the prion protein genes. These code for a normal prion protein in the cell (PrP^{C}). which has 254 amino acids with each codon in the gene encoding for a specific amino acid at a particular location on PrP^{C}. PrP^{C} can be converted to scrapie prion protein molecule (PrP^{Sc}) in infected sheep which, when it accumulates in the central nervous system, causes disease. The susceptibility of sheep to this conversion, and thus to scrapie, is strongly associated with certain polymorphisms at codons 136, 154, and 171. It is thought that there are at least two groups of scrapie TSE strains, one of which is influenced primarily by the amino acid at codon 136 and the other group by the amino acid at codon 171. Within these there may be subtypes, as resistance to some 136-type TSEs can be affected by the amino acid at codon 154.[31]

- At codon 136 valine (V) is linked to scrapie susceptibility and alanine (A) is linked with resistance
- At codon 154 histidine (H) is linked to susceptibility and arginine (R) to resistance
- At codon 171 glutamine (Q) and histidine (H) are linked to susceptibility and arginine (R) to resistance.

Table 23.2 PrP genotype and susceptibility to scrapie in National Scrapie Program (NSP) in Great Britain

NSP Type	Main characteristic	Genotypes	Comments
1	**ARR homozygous**	ARR/ARR	Genetically most resistant
2	**ARR heterozygous non-VQR**	ARR/AHQ ARR/ARQ ARR/ARH	Sheep that are genetically resistant to scrapie, but will need careful selection when used for further breeding
3	**Non-ARR and non-VQR**	AHQ/AHQ ARQ/AHQ AHQ/ARH ARH/ARH ARQ/ARH ARQ/ARQ	Sheep that genetically have little resistance to scrapie and will need careful selection when used for further breeding. Group 3 risk varies and can depend on breed, e.g. ARQ/ARQ Suffolk are highly susceptible. ARQ/ARQ Cheviots relatively resistant
4	**ARR/VQR heterozygous**	ARR/VRQ	Sheep that are genetically susceptible to scrapie and should not be used for breeding unless in the context of a controlled breeding
5	**VQR and non-ARR**	AHQ/VRQ ARQ/VRQ ARH/VRQ VRQ/VRQ	Sheep that are highly susceptible to scrapie and should not be used for breeding

Adapted from Refs 7 & 17.

- The notations used for descriptions of the prion protein (PrR) genotype vary in different countries
- The susceptibility of sheep to scrapie is strongly associated with polymorphisms at codons 136, 154, and 171 in the prion protein gene
- The amino acids associated with these polymorphisms are Alanine, Valine, Histidine, Arginine and Glutamine

- In the description of the PrP genotype these are given the letters A, V, H, R and Q respectively
- The PrP genotype is listed in the order of codon 136 followed by 154 and then 171
- The amino acid at each codon is listed according to the letter designation for each of the two alleles separated by a backslash. Examples are ARR/ARR or ARR/VQR. These could also be expressed as $AA_{136}RR_{154}RR_{171}$ and AV_{136} RQ_{154} RR_{171}
- In sheep in the United States the polymorphisms at codon 171 are the major determinant of scrapie susceptibility. Polymorphisms at codon 154 play a minor role and are usually not listed as part of the PrP genotype
- Genotypes in the US are usually referred to using the letters of the amino acids in numerical order codon 136 followed by codon 171
- The examples above would be AA RR, and AV RR
- They can also be referred to using the codon number followed by the corresponding amino acid 136AA, 171RR and 136AV, 171RR or the amino acid followed by the codon
- Often only the amino acids at codon 171 are listed.

Of the possible alleles from these polymorphisms only five, ARR ARQ, VRQ, AHQ, ARH, are commonly seen and the relationship between PrP genotype and susceptibility to scrapie is shown in Table 23.2 using the groupings of the British National Scrapie Plan.

It can be seen from Table 23.2 that in the Britain, the VQR allele confers the greatest degree of susceptibility and that ARR is associated with resistance. Estimates that quantify risk in the British national flock based on genotypes of the sheep, and those of scrapie affected sheep are available but they are not strongly concordant.[16,17] There is also an effect of PrP genotype on incubation period with the most susceptible genotypes (VQR) having the shortest incubation period and dying of scrapie at a younger age.

The frequency and distribution of the various PrP genotypes varies considerably between flocks and between breeds of sheep.[7,17,32]

For example, in 15 flocks scrapie-affected flocks, the flock frequency of sheep with VQR-containing genotypes ranged from 2 to 82%.[17]

Table 23.3 Scrapie susceptibility and genotype as defined by the USA scrapie eradication plan[27]

Genotype	Susceptibility
1. AA RR	Sheep which are resistant
2. AA QR	Sheep which are rarely susceptible
3. AV QR	Sheep that are susceptible to some scrapie strains that are believed to occur with low frequency in the USA
4. AA QQ	Sheep which are highly susceptible
5. AV QQ	Sheep which are highly susceptible
6. VV QQ	Sheep which are highly susceptible

There are also some marked between-breed differences in susceptibility with the same PrP genotype.[27]

Susceptibility in the Suffolk breed appears less complex than in other breeds and is strongly associated with sheep that are homozygous for glutamine at the 171 codon (171QQ) of the PrP gene but is rare in sheep heterologous for glutamine and arginine (171QR) or homozygous for arginine (171RR) at codon 171.[33] Suffolks are the predominant breed affected with scrapie in the USA. They lack the VRQ allele and the ARQ/ARQ genotype is the genotype that confers the greatest susceptibility[24,27,34] The association between genotype and susceptibility as defined in the scrapie eradication plan of the USDA in the USA is shown in Table 23.3.

Factors other than the PrP genotype influence susceptibility to scrapie as not all sheep with a susceptible genotype challenged with scrapie subsequently develop the disease. Also there are some breed differences in the level of resistance or susceptibility conferred by a given genotype. For example ARQ/ARQ Suffolk sheep are highly susceptible to scrapie whereas ARQ/ARQ Cheviots relatively resistant. Breed differences in PrP genotype scrapie disease linkage and disease pattern differences with

atypical strains of scrapie may be associated with polymorphisms in the PrP gene promoter.[35]

There is little information on the genetics of scrapie in **goats**. There is high variability in the goat PrP gene which possibly can be exploited to select for goat-specific scrapie-resistant PrP genotypes but as yet these are not known.[36]

23.2.2.1.4

Risk factors

23.2.2.1.4.1

Exposure factors

There is a dose–response relationship in naturally occurring scrapie.[10] The high incidence in some Icelandic flocks is attributed to a high level of exposure, resulting from a long winter housing period with a higher risk for disease in lambs born in the winter housing period.

Factors that influence exposure risk will vary with the management systems, which can vary markedly between countries. With that caveat, risk factors that have been identified in case control studies[13,28,37] include:

- A higher risk for scrapie in larger flocks and in pedigree flocks
- A greater risk in flocks that lamb communally in group pens compared to those that in those that lamb in individual pens or outside on pasture
- A greater risk in flocks that disposed of the placenta in the compost and spread sheep compost on the land
- A lower risk in flocks where cow compost is spread on the land
- A greater risk in flocks that purchased replacement sheep through the market
- A greater risk where different flocks share pastures or rams.

23.2.2.1.4.2

Age at exposure

Lambs exposed at birth have a shorter incubation period and higher risk for scrapie than lambs exposed at 6–9 months of age. Similarly, lambs or goats removed from infected dams at birth to a scrapie-free environment have a lower incidence of scrapie than those removed at later times.

23.2.2.1.4.3

Infection status of parents

Lambs born to affected ewes are at increased risk for scrapie, and the offspring from an infected ewe and an infected ram are at greater risk than those born from an infected ewe and an uninfected ram. However, even in high-incidence herds a considerable proportion of disease cannot be attributed to parental scrapie status and results from horizontal transmission.[10] Also the number of genetically susceptible sheep in an affected flock can increase the infection pressure.

23.2.2.1.4.4

Goats

Scrapie in goats is rare and most cases arise in goats that are in close contact with infected sheep. Scrapie can spread from goat to goat with no sheep contact.[18]

23.2.2.1.5

Experimental reproduction

The agent is present in the brain, spinal cord, lymph nodes, intestinal tract tissue, and spleen of infected sheep, and has been extracted from sheep and goat brain. Experimentally, the disease can be transmitted to sheep, goats, mice and other laboratory animals using these tissues, and by a variety of routes of inoculation. The experimental disease has a long incubation period that varies with the strain of the agent and the genetics of the recipient. Transmission of the disease to sheep has also been effected by the oral or intracerebral administration with fetal membrane material from known infected ewes. Accidental transmission is recorded following vaccination against louping-ill, with vaccine contaminated by the agent of scrapie, and resulted in widespread dissemination of the disease.

23.2.2.1.6

Pathogen risk factors

The scrapie agent can be maintained in tissue culture, and infectivity is retained with passage.[21] It can also be perpetuated in experimental animals. Infectivity also survives for remarkable periods in dead and formalinized tissues; infected brain homogenates buried in soil for 3 years retain their infectivity.[5] It is highly resistant to physical and chemical influences and can survive decontamination processes that are effective against conventional viruses.[38] It is capable of withstanding the usual virucidal procedures and is not destroyed by boiling, by rapid freezing and thawing, or by exposure to ether or

20% formalin. Conventional heat treatments may reduce infectivity, but the agent is remarkable resistant to heat[39] and steam sterilization at 27psig (132°C) is required to totally destroy it. Chemical inactivation can be achieved with sodium hypochlorite providing 2% (20000ppm) of available chlorine acting for 1 hour, and by 4% sodium hydroxide.

23.2.2.1.7

Economic importance

Scrapie is of major concern to pedigree flocks and, if present and public, will curtail the sale of sheep and effectively result in the dissolution of the flock. Some countries have, or have had, eradication schemes. The disease is also of major international importance because of the embargos maintained by several countries against sheep from enzootic areas. The recent occurrence of bovine spongiform encephalopathy in Great Britain and one theory of its putative origin from scrapie has emphasized the need for control of this disease.

23.2.2.1.8

Zoonotic implications

There is no evidence for transmission of scrapie to humans or for a risk to public health.[40] However the concern that BSE might be established in sheep as a result of feeding of infected meat-and-bone meal, and be indistinguishable from scrapie, has led some countries to establish an active TSE surveillance program in sheep. As part of this, all sheep that are over 18 months of age and intended for human consumption are tested at slaughter by a rapid test for scrapie and BSE.

23.2.2.2

PATHOGENESIS

1443
1444

In both sheep and mice, the agent shows a predilection for tissues of the lympho reticular system where it replicates during the incubation period before invadingthe nervous system. In naturally infected sheep, replication begins in the tonsil, retropharyngeal and Peyer's patches and gut-associated lymphoid tissue, which probably reflects the oral route of infection. PrP^{Sc} subsequently becomes disseminated to other lymph nodes and the spleen. There may be a considerable period, ranging from 14 months to 7 years, before there is infection of the brain, and during this during infection in the lymphoreticular system probably provides the reservoirfor maternal and horizontal transmission.[24,41,42] The action of the PrP genotype may be to delay neural invasion, in which case it is possible that a non-clinical carrier state may exist for scrapie.[43]

How the scrapie agent reaches the central nervous system is not certain but is probably through infection of the autonomic nervous system. Gut-associated lymphoid nodules in the Peyer's patches have a substantial network of nerve fibers and are probably the site for neuroinvasion and the scrapie agent has been detected in lymphoid nodules of the Peyer's patches of the gut as early as 5 months after oral infection.[44]

Infection in the brain of sheep is initially in the diencephalon and medulla oblongata, with subsequent spread and replication in other areas of the brain. Characteristically, there is a non-inflammatory, vacuolar degeneration of gray matter and the presence of PrP^{Sc} in scrapie-associated fibrils. Infection results in the post-translational modification of this protein so that it becomes resistant to proteinases and to normal clearance and consequently accumulates in the cell.

PrP^{Sc} is also present in the placenta and is present in the trophoblast cells of the placentomes but not in the endometrium, myometrium, associated nerve plexuses nor is it in fetus. The presence of PrP^{Sc} in the placenta is determined by the fetal PrP gene and PrP^{Sc} is not present in the placenta of fetuses carrying one or two ARR alleles.[24,34]

23.2.2.3 ## CLINICAL FINDINGS

23.2.2.3.1 ### Incubation

The incubation period varies from several months to several years. Scrapie is a non-febrile disease and the onset is insidious, but as the disease progresses clinical signs become more obvious and severe. The **clinical course** is protracted, varying from 2 to 12 months, but lasting in most cases for about 6 months. Affected animals usually show **behavioral change, tremor, pruritus, and locomotor disorder**.

23.2.2.3.2 ### Early signs

The earliest signs are transient, nervous phenomena occurring at intervals of several weeks or under conditions of stress. These episodes include sudden collapse and sudden changes of behavior, with sheep charging at dogs or closed gates.

Rubbing and biting at the fleece then begin but are often unobserved because of their infrequent occurrence. The apparent **pruritus** is manifested chiefly over the rump, thighs, and tail base. The poll and dorsum of the neck may also be involved and, less

commonly, the neck in front of the shoulder and the ribs behind the elbow. The affected areas have approximate bilateral symmetry. In this early stage a stilted gait is often observed. A general loss of condition may also be observed as an early sign, although the appetite may not be severely affected.

23.2.2.3.3

Advanced cases

More advanced cases show intense pruritus, muscle tremor and marked abnormalities of gait, and severe emaciation. **Persistent rubbing** causes loss of wool over the areas mentioned above. Scratching with the hindfeet and bitingat the extremities also occur. Hematoma of the ears and swelling of the face may result from rubbing. Light or deep pressure, pinpricking, and application of heat or cold may elicit the characteristic ‘nibbling or scrapie scratch’ reaction, during which the animal elevates the head and makes nibbling movements of the lips and licking movements with the tongue. The sheep's expression suggests that the sensations evoked are pleasant ones. The reaction may not be observed consistently, often disappearing when the sheep is excited or in new surroundings.

Simultaneously with the development of pruritus there is serious **impairment of locomotion**. Hindlimb abnormalities appear first. There is incomplete flexion of the hock, shortening of the step, weakness, and lack of balance. The sense of spatial relationship appears to be lost and the sheep is slow to correct abnormal postures. Adduction occurs during extension, and abduction during flexion. When the animal is attempting to evade capture, gross incoordination of head and leg movements is likely and the animal often falls. Convulsions, usually transient but occasionally fatal, may occur at this time.

General hyperexcitability is evident. In the animal at rest an intermittent nodding and jerking of the head and fine tremor of superficial muscles may also be observed. In some cases, nystagmus can be produced by rotating the head sideways. Other clinical signs include inability to swallow, although prehension is unaffected, vomiting, loss of bleat, and blindness. A change of voice to a trembling note is often most noticeable.

Anorexia is not evident in most cases until the last 4–5 weeks and results in rapid loss of body weight. Abomasal distension and impaction occurs in some cases. Pregnancy toxemia may occur as a complication in pregnant ewes during this stage of scrapie. Finally, the sheep reaches a stage of extreme emaciation and inability to move without

becoming readily fatigued. Sternal recumbency follows and lateral recumbency with hyperextension of the limbs is the final stage. Pyrexia is not evident at any time.

In a detailed study in 129 sheep with scrapie the proportional occurrence of signs was: hindlimb ataxia 71%; head tremor 61%; altered mental status 57%; positive nibble reflex 51%; crouching position 51%; teeth grinding 44%; low head carriage 38%; body condition score of less than 1.5, 38%; and conscious proprioceptive deficits of limbs 36%.[45] The occurrence of clinical signs were examined in relation to PrP genotype. The nibble reflex was strongly associated with PrP genotypes ARQ/ARQ and ARQ/ARH.

In goats, the clinical course in naturally occurring cases lasts from 2 to 24 weeks. Clinical signs are similar to those in sheep, and hyperesthesia, ataxia and pruritus are common, but loss of weight is less common.[22] In lactating goats the first sign may be a reluctance to permit milking. Dribbling and regurgitation of ruminal contents are also recorded in one-third of cases.

In most countries the disease is reportable to government authorities.

23.2.2.4

CLINICAL PATHOLOGY

There are no changes in hematologic or serum biochemistry parameters. It has been suggested that the disease could be diagnosed antemortem by electroencephalography but this has been disputed.[42]

Until recently there has been no antemortem test for scrapie; however, PrP^{Sc} can be detected in cells by immunohistological methods and is present in the lymphoid tissue of sheep with scrapie in the preclinical phase of the disease. **Tonsillar biopsy** has detected PrP^{Sc} in lambs of susceptible genotypes as young as 5 months of age[46] and in the tonsils of non-challenged susceptible lambs at 9–10 months of age that were born and maintained in a scrapie environment.[47] However, tonsil biopsy requires general anesthesia and is not a practical on-farm technique. Biopsy of lymphoid follicles in the third eyelid is more practical, requires only restraint and local anesthesia, and can be a valuable tool for the preclinical diagnosis of scrapie in surveillance programs.[48]

In scrapie positive sheep, PrP^{Sc} can usually be detected by 14 months. A sample of a single protuberance on the palpebral side of the third eyelid will usually give sufficient follicles for analysis.[49] Histamine-containing eyedrops improve the success of collecting a sample with adequate follicles for examination.[50]

1444 1445

23.2.2.5

NECROPSY FINDINGS

Significant gross findings are restricted to traumatic lesions caused by rubbing, and to emaciation and loss of wool; gross distension of the abomasum has been recorded in some natural cases.

The essential histopathological lesion in scrapie is the **vacuolation of gray matter neuropil** in the spinal cord, medulla, pons and midbrain, and the consequential Wallerin degeneration in dorsal, ventral and ventrolateral columns of the spinal cord, and in nerve fibers in the cerebellar peduncles and the optic nerve. In addition, there is degeneration of the cerebellar and hypothalamoneurohypophyseal systems. There are different strains of the scrapie agent that can result in differing clinical signs and pathology.[51] Scrapie-associated fibrils are present in infected brain. Histological findings are diagnostic in many cases but can be supplemented with the immunodetection of PrP^{Sc} in brain tissue by in situ immunohistochemistry and Western immunoblots.[51] The breed of the sheep affects the magnitude of neuropil vacuolation and variation also is associated with the PRP genotype within breeds.[52]

Atypical strains of scrapie (Nor98) are recognized that differ from the usual strains in their vacuolation patterns and their disease-specific, protease-resistant PrP^{Sc} disposition patterns.[53] These strains can also produce disease in PrP genotypes not normally affected, including Prp genotype ARR/ARR.

23.2.2.5.1

DIFFERENTIAL DIAGNOSIS

The characteristic signs of behavioral change, tremor, pruritus, and locomotor disorder occurring during a period of prolonged illness should suggest the possibility of this disease. The long incubation period, slow spread and high case fatality rate should also be considered when making a diagnosis. Diseases that may require differentiation include:

23.2.2.5.1.1

Diseases with signs of nervous dysfunction:

- Louping ill
- Pregnancy toxemia
- Rabies

- Pseudorabies
- Visna.

23.2.2.5.1.2 Skin diseases:

- External parasites
- Wool loss.

23.2.2.5.1.3 Treatment

No treatment has proved capable of changing the course of the disease.

23.2.2.6 CONTROL

23.2.2.6.1 Individual flocks

The maintenance of a closed ewe flock is critical to the control of this disease. If ewes need to be purchased from outside flocks they should be from certified flocks or better still, selected on by PrP genotype testing for 171RR or 171QR genotype. The rams should be 171RR or 171 QR rams. Ewes should be isolated at lambing and lambed individually with disposal of placenta by burning.

23.2.2.6.2 National eradication

In countries that do not have the disease, and where it is inadvertently introduced with imported sheep, the approach is slaughter eradication of the infected flock and all in-contact animals. The aim is to eliminate the disease from the country and the approach is usually successful because it has the full support of the sheep industry and the government.[8]

23.2.2.6.3 Flock eradication

The eradication of scrapie in countries where it is enzootic has less chance of success. Eradication programs vary and may involve the whole flock or just the family lines of the infected sheep. Programs in the United States since 1952 have varied from compulsory slaughter eradication of the affected flock and source flocks, to bloodline eradication, and finally from discontinuation to a voluntary certification scheme.[18]

During this period there was no antemortem diagnostic test for scrapie and the identification of infected farms and flocks relied upon owners submitting suspect or clinical cases for postmortem and histological diagnosis. Owners are unlikely to put their flocks at risk if there is inadequate compensation for the results of their action, if they perceive that other flock owners are not cooperating with the control program, or if they question the validity of the eradication policy, whichis attested to by the experience in the United States.

Iceland is currently attempting an eradication program which involves depopulation of infected farms and areas. The farms are left without sheep for a 2-year period during which there is extensive cleaning and disinfection of the farm area prior to repopulation with scrapie-free sheep. The program is a national thrust but very expensive.[54] This approach has also been apparently successful in virtually eliminating, if not eradicating the disease in Iceland. Norway is also attempting eradication in a similar manner. In both countries the disease was geographically clustered.

23.2.2.6.4

Genetic control and national programs

The occurrence of scrapie and the concern for BSE in sheep has led many countries to develop of national breeding programs for the control of scrapie and potential BSE. Examples are the National Scrapie Plan in the UK and the National Scrapie Eradication Program in the US National Scrapie Plan. The overall aim is to identify sheep genetically resistant to scrapie on the basis of their genotype (ARR) and to and breed them so as to create a national flock with scrapie resistance. Genetic testing will allow the selection of resistant sheep for breeding and the culling of susceptible sheep, particularly in breeds such as the Suffolk where the genetics of susceptibility appear relatively simple.

The **UK** has a Voluntary **National Scrapie Flocks Scheme** and a National Scrapie Plan which, under EU regulations, has recently become compulsory for flocks that have had a case of scrapie after July 2004. Under the Compulsory Scrapie Flocks Scheme farmers with confirmed scrapie cases on their farms will either have their sheep flocks genotype tested so that those animals more susceptible to disease (groups 3 to 4) can be identified and removed or the whole flock slaughtered and disposed of. All goats on affected holdings will be slaughtered and disposed of. Testing of breeding rams will also become compulsory for all purebred flocks and any other flocks producing and selling homebred rams for breeding. All rams carrying VRQ PrP genotypes will be slaughtered or castrated. Allied to this will be a voluntary ewe-testing scheme.

A mathematical model of the program has examined the time that it would take to eliminate scrapie from the national flock.[55] The results suggest eradication feasible but the process could take decades and would be expensive. Surprisingly whole flock culling was more efficient in terms of time to eradication than genetic typing and selective culling. Not surprising was the finding that the **most important factor** influencing the efficacy of control at the national level was the ability to identify affected flocks. It was suggested that investing money in obtaining better notifications and in conducting trace backs and active surveillance of animals slaughtered for human consumption and animals found dead on farms would be a good investment.

In the **USA**, all breeding sheep must be individually identified with a unique flock and individual number. The **Scrapie Flock Certification** program monitors flocks over time and the assigns certified status to flocks with no evidence of scrapie. While this program has strict requirements of identification and reporting it is not based on genetic testing.

1445

1446

The **USA** also has a **USDA Genetics Based Flock Clean-Up and Monitoring Plan.** This program targets scrapie infected and source flocks. The sheep in these flocks are genotyped, sheep with susceptible genotypes are removed (as are all goats) and the flock is placed under surveillance for five years. Flocks that are exposed to scrapie are placed on a monitoring program and if scrapie is detected would begin the genetics based clean up program. The eyelid biopsy test can be used for selected monitoring for preclinical disease in these flocks.[48]

There is concern that breeding for the selection for certain PrP genotypes and reduction or elimination of other PrP genotypes could affect other **desirable genetic characteristics** and reduce the overall ‘genetic pool’. This will need to be determined for individual breeds but preliminary analyses, that have involved several breeds, suggest that reproductive traits, muscle mass, wool quality, live weight gain, carcass characteristics, is not affected, at least in some breeds.[56–58]

There has also been concern that **rare breeds** could be threatened in the face of an occurrence of scrapie and flock with subsequent disposition of the flock based on PrP genotype. Interestingly there is a good representation of ARR with some breeds having very high frequencies.[59]

23.3 BOVINE SPONGIFORM ENCEPHALOPATHY (BSE)

Bovine spongiform encephalopathy (BSE) is an afebrile neurological disorder affecting adult cattle. It is a subacute transmissible spongiform encephalopathy and is believed due to a single stable cattle-adapted strain of a scrapie-like agent and occurred as the result of the exposure of cattle to animal protein feeds containing the scrapie agent.

23.3.1 Synopsis

23.3.1.1 Etiology

An agent related to the transmissible agent of scrapie. Major concern for zoonotic potential

23.3.1.2 Epidemiology

Has occurred as an epidemic in Great Britain associated with the feeding of infected meat-and-bone meal. Sporadic in other countries

23.3.1.3 Clinical findings

INon-febrile disease of adult cattle, with long clinical course. Disturbance in behavior, sensitivity, and locomotion

23.3.1.4 Clinical pathology

None specific

23.3.1.5 Diagnostic confirmation

Histology, demonstration and prion protein

23.3.1.6 Treatment

None

23.3.1.7 Control

Slaughter eradication. Avoidance of feeding ruminant-derived protein to ruminants

The disease is of considerable importance mainly because it has zoonotic potential and has spread to many countries. The cost of control is very high.

23.3.2 ETIOLOGY

BSE is a prion-associated transmissible spongiform encephalopathy.

The stability of the lesion profile in cattle and the lesion profiles in mice strongly suggests that the epidemic in Britain, and the subsequent extended epidemic in other countries, is due to a single stable cattle-adapted strain of a scrapie-like agent.[1] There is debate as to whether the transmissible agent is a strain of scrapie that has modified to infect cattle or whether it originated from a sporadic spongiform encephalopathy pre-existent in the cattle population. There is evidence of characteristics that distinguish it from conventional scrapie strains.[2,3] In view of the high susceptibility of certain African ungulates and zoo carnivores to infection it has also been postulated that the agent could have entered into meat-and-bone meal from the carcass of an animal that died in a zoo or a safari park in the UK.[4] A further hypothesis promotes meat and bone meal from the Indian sub-continent as a source. The British government has conducted several enquiries into the source of the agent and the cause of the out break including the Phillips report in 2000,[5] and the Horn report in 2001[6] but there has been no conclusion and the source may never be known.

The mass exposure of cattle in Great Britain to this agent, and the subsequent development of a disease epizootic in cattle in the latter half of the 1980s and the early 1990s is believed to have been the consequence of a change in the method of processing of meat-and-bone meal (MBM) prepared from slaughter sheep (or cattle) latently infected with the agent so as to allow it to persist in this feed.[6–8] 1446 1447

Subsequent recycling of the agent in meat-and-bone meal prepared from latently infected slaughter cattle amplified its occurrence.

23.3.3 EPIDEMIOLOGY

23.3.3.1 Occurrence

23.3.3.1.1 Geographic occurrence

BSE was first described in Great Britain in 1987 but the BSE Inquiries considered it likely that there had been several undetected cycles of BSE in the South West of England in the 1970s and early 1980s. Following its description in 1987, the disease developed to an epizootic with over 183000 cases, of which more than 95% were detected before 2000. The epidemic peaked at an annual total of more than 37000 clinical cases in 1992. The disease was recognized in Northern Ireland, in 1998 and in the Republic of Ireland

in 1999. The disease was subsequently recognized in Switzerland, Portugal and France in the early 1990s and is now widespread.

Cases have occurred in imported British cattle in Oman and the Falkland and Channel Islands Countries that have had cases of BSE in native cattle are Austria, Belgium, Canada, Czech Republic, Denmark, Finland, Germany, Greece, Ireland, Israel, Italy, Japan, Luxembourg, Netherlands, Poland, Portugal, Slovakia, Slovenia, Spain, Switzerland, United Kingdom, and the United States of America.[9]

The OIE Terrestrial Animal Health Code describes five BSE risk categories for countries. In order of increasing incidence of BSE these categories are: BSE free, BSE provisionally free, minimal BSE risk, moderate BSE risk, high BSE risk. These classifications can be important in trade.

23.3.3.1.2

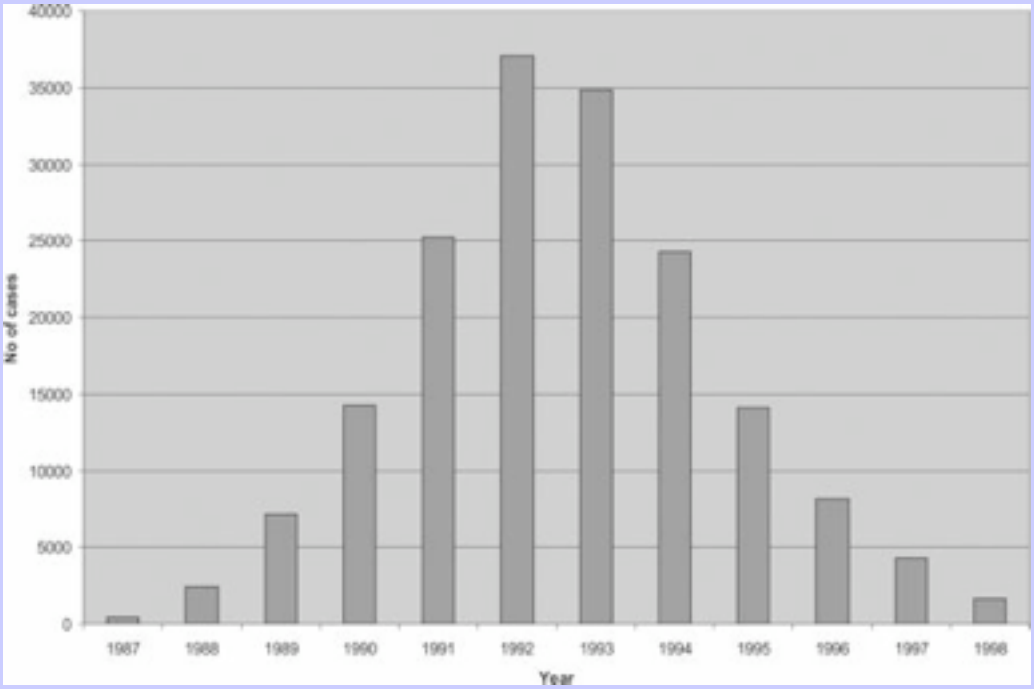
Occurrence in cattle

23.3.3.1.2.1

Great Britain

In Great Britain, the first known clinical case probably occurred in 1985. The annual incidence subsequently increased and the disease became a major epizootic in the late 1980s. The disease was declared notifiable, and a statutory ban on the feeding of ruminant-derived protein to ruminants was introduced in 1988. A more extensive ban on feeding any animal protein to any agricultural animal was later implemented to avoid feed cross-contamination. The annual incidence peaked in 1992 and has fallen every year since to produce a bell-shaped epidemic curve at approximately the year 2000, with some cases every year since. The reduction from the peak in 1992 is attributed to the 1988 ruminant-feed ban with the delay in response an effect of the incubation period of this disease. Britain has had the greatest number of affected cattle and provides the most information on the disease.

Fig. 23.1 Annual reports of incidence of BSE in the UK (1987–1998).



23.3.3.1.2.2

Herd type

The great proportion of cases have occurred in **dairy and dairy crossbred herds**, and by 2002 61.7% of dairy herds in Great Britain had experienced one or more cases.[10] In contrast, 17.1% of **beef** herds had cases in the same time period. There has been no apparent breed predisposition. In both herd types, the risk for cases increased significantly with increasing herd size. A significant proportion of the cases in beef cattle herds have occurred in animals purchased into the herds from dairy herds. The reason for this difference in herd type is believed to be the greater use of concentrates in dairy cattle.

The disease has occurred in all regions of the country but was most prevalentin southwest England. Although the disease developed to an epizootic within the country, the disease does not occur as an epizootic within affected herds and most experience either single cases or a limited number of cases. The average **within-herd incidence** has remained below 2% since the disease was first described.

23.3.3.1.2.3

Northern Ireland and Republic of Ireland

In Northern Ireland the disease was recognized in 1998 and in the Republic of Ireland in 1999 but **epizootic disease** occurred Great Britain and Northern Ireland.[10–12] The epidemiological features in both countries were similar to that in Great Britain, but the incidence has been lower. In Northern Ireland the incidence was approximately one tenth of that in Britain.[11] The yearly incidence of the disease peaked in 1994 in Northern Ireland but jumped unexpectedly in the Republic of Ireland in 1996 to 1998 and has remained high since. The source of infection in both countries is believed to have been meat-and-bone meal imported from Great Britain. In the Republic of Ireland there has been geographic clustering with a higher incidence in two counties[13] possibly associated with the location of feed suppliers.

23.3.3.1.2.4

European continent and Iberian Peninsula

On the European continent the disease was recognized in Switzerland in 1999 and shortly after on the Iberian peninsula in Portugal. Both countries showed a case incidence with evidence of an epidemic curve. However this was not mirrored in European Union (EU) member states in the continent, where only sporadic cases were reported in the 1990s, and it appears that the disease in this region was unrecognized, under-reported, and was more widespread than recorded.[14,15] Apparently cattle with typical clinical manifestations and fallen stock with clinical signs that should have led to a suspicion of BSE were misdiagnosed or not reported.[16]

Switzerland established a surveillance system in 1999 testing fallen cattle, emergency slaughter and normal cattle using Prionics western blot rapid testing methods.[17] This surveillance method was rapidly adopted EU member countries so that all but two had recorded cases by the end of 2001. In France, between the first notified case in the 1991 and the establishment of mandatory testing in 2000 there were 103 cases detected by passive surveillances but it is estimated that 301200 cattle were infected with BSE during this period.[18]

23.3.3.1.2.5

North America

Canada experienced a case of BSE in a cow imported from Great Britain in 1993 but the first case in an indigenous Canadian cow occurred in 2003 in Alberta. Trace back

on 40 herds and slaughter of over 2000 suspects were all negative. The molecular profile of the BSE agent from this case was very similar to the UK BSE strains and had no relation to the agent associated with **chronic wasting disease** in deer and elk.[19] In 2003 a Canadian cow that had been exported to the USA as a young cow developed complications at parturition, was shipped as a non-ambulatory cow, and was discovered as a BSE case under a routine monitoring program of downer cows.[20] Canada had two more cases of BSE in 2005. The US had had a case in a native born cow in 2005. Trace backs and slaughter study of birth contemporaries have proven negative for BSE. Affected animals in both countries were born before the ban on feeding MBM in 1997.

23.3.3.2

Age incidence

BSE, like scrapie, has a **long incubation period**, 2.5 to at least 8 years and possibly for the lifespan of cattle, and is a disease that affects mature animals. Epidemiological studies suggest that most affected cattle have been infected as calves.[7] Risk is greatest in the first 6 months of life and between 6 and 24 months of age risk is related to feeding patterns of proprietary concentrates. Adult cattle are at low risk for infection.[21]

The **modal age at onset** of clinical signs is between 4 and 5 years but there is a skewed distribution with the youngest age at onset recorded at 22 months and the oldest at 15 years.[10,22] During the course of the outbreak in the UK there has been a change in the age distribution of cases in both Britain and Northern Ireland, consistent with a sudden decrease in exposure as a result of the bans on ruminant protein feeding. The clinical course is variable but the case fatality is 100%. There is a variation in risk associated with the calendar month of birth related to seasonal differences in calf management and exposure to ruminant protein in calf feeds.[11]

23.3.3.3

Other species

Spongiform encephalopathies have been identified in seven species of **ungulates** in zoos or wildlife parks in Great Britain since the occurrence of the disease in cattle. These animals had been fed meat-and-bone meal but the apparently shorter incubation period suggests that they might be more susceptible to infection than cattle and there is evidence for horizontal transmission.[23]

Feline spongiform encephalopathy (FSE) is also recorded in **domestic cats** in Great Britain since 1990 and in zoo felids. The **zoo felids** had been fed cattle carcasses unfit for human consumption, or the zoo had a history of BSE in exotic ruminants and fed culled carcasses to other zoo animals.[24,25] Transmission studies in mice with the agents associated with these encephalopathies in zoo ungulates and felids suggest that they are the same strain as causes BSE.[3] The initial concern that there would be an outbreak of FSE in domestic cats did not occur and only 89 cases were confirmed to the end on 2003.[26]

23.3.3.4 Method of natural transmission

23.3.3.4.1 Ingestion of meat-and-bone meal

The initial epidemiological studies suggested that the disease in the UK was an extended common-source epidemic and the only common source identified in these initial studies was the feeding of proprietary concentrate feedstuffs.[7] Epidemiological studies also suggested that presence of meat-and-bone meal in proprietary concentrates was the proxy for affected cattle to have been exposed to a scrapie-like agent,[7,10,11] and this conclusion is supported by case-control studies examining feeding practices to calves that subsequently developed the disease.[27] This hypothesis explains **breed differences** in incidence, as concentrates are not commonly fed to beef calves in the UK, and also can account for geographical differences in incidence. The oral route of challenge is known to be an inefficient route for the transmission of the agents associated with spongiform encephalopathies[28] and this is believed the reason for the low within-herd incidence of the disease in the face of a common exposure.[27]

Meat-and-bone meal is manufactured by the rendering industry from tissues discarded in slaughterhouses, and also from down and dead livestock. The outbreak of BSE in Britain was temporarily preceded by a change in the method of processing of meat-and-bone meal to a continuous process with a cessation of the use of hydrocarbon fat solvents. It is postulated that this change, coupled with the high sheep to cattle ratio in Great Britain, allowed the greater survival of a scrapie-like agent in scrapie-infected sheep carcasses processed to meat-and-bone meal to reach a level that was infective for cattle. An alternate hypothesis is that the agent came from existing, but low incidence and unrecognized, cases of BSE. The initial exposure occurred in 1981/82 and,

subsequently, the agent recycled from infected cattle carcasses and offal used in the preparation of meat-and-bone meal.[8,29,30]

Rendering procedures have subsequently been devised to minimize survival of the agent.[31]

The marked fall in disease incidence following the introduction of the feed ban in 1987 in the UK substantiated the importance of ingestion of meat-and-bone meal as the major method of infection. Bans in Europe were largely introduced in 1990.

23.3.3.4.2

Born-after-the-ban

In the UK and in other countries a number of cattle that were born-after-the-ban (BAB, French acronym NAIF) have developed the disease. Most of these were born in the years immediately following the ban and their numbers have decreased in subsequent years but still continue at low levels.[32,33] A case–control study found that vertical or horizontal transmission was not an important cause of these cases.[34] It is believed that meat-and-bone meal that was already in the food chain at the time, in mills and on the farm, was fed untilit was depleted.

In several countries the occurrence of born-after-the-ban cases has been geographically clustered, and also associated with certain birth-cohorts.[32–34,36] In the UK the clustering was related to areas with high concentrations of pigs and poultry and it is believed that there was cross-contamination of feedstuffs in feedmills.[37] This is certainly possible with an infective dose of one gram of less.

More recently there has been concern at cattle in the UK that have developed BSE but that were born after the implementation of the reinforced feed ban in 1996 (BARBs). To 2005 there have been approximately 100 cases. Again there is no evidence of maternal or lateral transmission and the inadvertent use of illegal feed material residual on farms is suspected.

23.3.3.4.3

Non-feedborne transmission

There is no epidemiological evidence for significant horizontal or vertical transmission of the disease in cattle[7,10,34] although the studies suggest that minor horizontal transmission may occur to birth cohorts of calves that subsequently develop BSE. This type of transmission is of minor importance to the perpetuation of the disease in a

country, but it may be of significance to human health and birth cohorts are included in trace backs of infection in the USA and Canada.

23.3.3.4.4

Vertical transmission

In the absence of other mechanisms of transmission, vertical transmission is not considered significant for the perpetuation of the disease in an epidemic form.[28] There is an **enhanced risk** for the disease in calves born to infected cows, and this is higher in calves born after the onset of clinical disease in the cow.[38,39] This may be the result of exposure, at birth, to high infectivity in birth products as there is no evidence for infection and transmission in embryo transplants.[39] However, no detectable infectivity has been found in placentas from cows with the disease.

1448

1449

A very elegant experiment that examined the risk for transmission of BSE via embryo transfer and which used recipient cattle sourced from New Zealand and donor cows clinically affected with BSE, bred to bulls that did and did not have clinical BSE, concluded, after a 7-year observation period on the progeny, that embryos were unlikely to carry BSE.[40]

23.3.3.5

Risk for occurrence of disease in countries

Changes in the method of processing meat-and-bone meal have occurred in countries other than the UK and scrapie occurs in sheep in other countries. However, the major risk for the occurrence of the disease in other countries is the importation of latently infected cattle and/or the importation of infected meat-and-bone meal. This risk can be substantially avoided by prohibiting the feeding meat-and-bone meal to cattle.

An assessment in 1996 of risk for the occurrence of BSE in the United States concluded that the potential risk of an epizootic was small and that there are substantial differences in the strength of the risk factors between the USA and the UK.[41] These result from differences in proportional numbers of sheep and cattle, differences in the nature of the beef and dairy industries, the type of animal used for beef production and the age at slaughter, differences in the prevalence of scrapie, differences in the rendering industry with a much lower proportion of rendered animal protein originating from sheep in the USA, and differences in the practice of feeding ruminant-derived protein in calf rations, which is uncommon in the USA.[12,41] An analysis published in 2004 concluded the same.[42]

Thus the risk of an outbreak similar to that in the UK was considered negligible. However a case in a native cow in the US has occurred in 2005. This, and the recent cases in Canada suggests that infected meat-and-bone meal was imported to the North American continent at some time. The cases in both countries occurred in cattle that were born before the ban on feeding meat-and-bone meal imposed in both countries in 1997.

Countries with largely pastoral cattle are at low risk.[43]

The International Animal health code of the OIE describes five BSE risk categories for countries based on the importation of cattle from at-risk countries, the importation of potentially infected meat-and-bone meal, the consumption of meat-and-bone meal by cattle and other animals, animal feeding practices, livestock population structure, rendering practices and the potential for recycling of BSE. In order of increasing incidence of BSE these categories are: BSE free, BSE provisionally free, minimal BSE risk, moderate BSE risk, high BSE risk.[44]

23.3.3.6

Experimental reproduction

While studies on the transmissibility and experimental reproduction of BSE were established before the occurrence of human cases of BSE (vCJD) they have been **critical in determining the risk** of cattle products for human disease and the risk for disease in other species.

In cattle, disease has been experimentally reproduced by oral, and intracerebral inoculation with infected cattle brain homogenates.

Oral, intravenous and intracerebral inoculation of sheep with infected cattle brain homogenates also results in disease. Disease has also been reproduced in goats and mink by parenteral challenge. In pigs, disease has been produced by intracerebral challenge with infected brain homogenates but not oral challenge. It has not been produced by any route of challenge in poultry and is not produced by oral challenge in farmed deer.[45]

The disease can also be produced and passaged in a variety of laboratory mice strains.

Some details of the results of the temporal infectivity of tissues produced in cattle by oral challenge with homogenates of infected brain tissue are given below under the heading pathogenesis.

In the initial oral challenge studies, cattle were challenged with a 100 g dose of brain homogenate that contained $10^{3.5}$ intracerebral/intraperitoneal LD/50/g of BSE.[46] There is currently a study in progress that examines the effect of dose on the incubation period of BSE and the distribution of infectivity. Dose rates of brain of 1 g have produced the disease and studies will continue with lower doses.

23.3.3.7

Infectivity of tissues

Brain, spinal cord and retina are tissues that are infective to cattle or laboratory animals from natural cases of BSE. The tissues that are infective to cattle or laboratory animals from experimentally infected cattle are brain, spinal cord, retina, distal ileum, bone marrow, trigeminal nerve and lingual lymph tissue.[46–48]

Parenteral injection of BSE brain:

- transmits from cattle to cattle, mice, goats, sheep, pigs, mink, guinea pig

Orally fed BSE brain:

- transmits from cattle to cattle, mice, mink, sheep and goats
- not to pigs or farmed deer

Other tissues including the major visceral organs, striated muscle and tissue common for human consumption were negative by mouse bioassay, indicating that no infectivity could be detected. These tissue are currently being re-examined for infectivity using the most sensitive assay known, intracerebral infection into the host species – in this case cattle. These studies are on-going but, at last report[49] have only confirmed the results of the negative mouse bioassays. There is no evidence of infectivity in milk based on the fact that calves suckling cows with clinical BSE do not themselves develop BSE when mature and also on the lack of infectivity with intracerebral injection of mice.[50,51]

Strongest evidence of absence of infection in milk is the study that examined and found no increase in incidence of BSE in calves born to dams with BSE that suckled these cows during clinical disease compared to calves that suckled clinically normal dams. There is species susceptibility (no barrier) strength in this study.

23.3.3.8

Economic importance

BSE is not of major economic significance to individual herds in countries in which it is endemic because of the low within-herd incidence. In most countries, compensation will cover cases detected by passive surveillance and, with active surveillance, most the costs if there is selective culling in affected and trace back herds.

However, it is arguable that this disease is the **most economically devastating** agricultural animal disease in the developed world.

The disease has been of major economic importance in the UK and is estimated to have cost £600 billion.[52] This has been due to the national cost associated with detection and control procedures, the cost of compensation and disposal of affected animals. These costs, along with the cost of loss of export markets are very high.

Worldwide, the public has developed an extreme concern for the public health risk associated with BSE infection in cattle and consequently all countries have been mandated or encouraged to develop active surveillance programs. Not to do so runs the risk of loss of overseas markets and loss of home consumption of beef in favor of other meats.

Further, the detection of a single case of BSE by these active surveillance programs results in loss of export markets for the country and a severe fall in cattle prices for countries that rely on exports in their cattle industries.

BSE is also arguably the disease that has been used most to influence trade in live cattle and cattle products with no science-base or attention to the internationally adopted OIE Terrestrial Animal Health Code. This largely because of the success of local political influence of ranches and farmers. 1449 1450

It is further arguable that the money spent, for reasons of public health, on this relatively minor zoonotic disease, by far outweighs its relative importance as a cause of human disease.

23.3.3.9

Zoonotic implications

Concerns that this disease could transmit to man were raised a very short time after its initial diagnosis. These unfortunately proved true in 1996 when a new form of CJD was reported. While, with the initial cases, there was reservation as to causality, studies showed

the agent associated with this disease is similar to that associated with BSE and the feline spongiform encephalopathies and there is now no doubt that this is a form of BSE in man. It differs from CJD in that it affects young people with a mean age onset in the third decade of life. In humans there is evidence for genetic susceptibility and all cases have been homozygous for methionine at codon 129. The disease has been termed **variant CJD** (vCJD).

The disease occurred in the UK despite the progressive bans on human consumption of beef products that contained infectivity that were implemented in 1998 and subsequently tightened further as new information on potential infectivity became available. It is possible that exposure of affected humans occurred in the early and mid 1980s, prior to the recognition of the disease. There was initially extreme concern that there would be a very large outbreak in humans. However, this has not occurred. The total number of deaths form vCJD in the UK has reached 150. The peak number of deaths occurred in the year 2000 and the outbreak appears to have reached a plateau and is possibly in decline[53] although the nature of the outbreak will be dependant on the range of incubation periods in humans.[54]

Also, cases of vCJD are more recently being reported from the European continent and the Iberian peninsula.

While there is no evidence of direct transmission to humans, veterinarians and animal handlers should take appropriate precautions when handling nervous system tissues of infected animals.

23.3.4 PATHOGENESIS

Information on the pathogenesis and development of BSE in cattle derives almost entirely from studies published from Britain in the 1990s that studied the spatial and temporal development of infectivity and pathological change in cattle after oral challenge with a 100 g dose of BSE-affected brain homogenate sourced from naturally clinically affected cattle.[49] The experimental cattle were killed sequentially following challenge and infectivity in tissues subsequently determined by initially by infectivity assays by intracerebral and intraperitoneal injection into panels of inbred mice, and subsequently by infectivity studies by intracerebral challenge of cattle to exclude any species barrier effects.

- Long incubation period (5 years)

- Oral infection
- Infection of Peyer's patches, to brainstem via vagus nerve
- Accumulation of abnormal prions destroys brain slowly

Following oral challenge of calves, infectivity was initially detectable in the distal ileum, in the Peyer's patches,[47] but no infection is demonstrable in other lymphoreticular organs.[49,55] Infectivity was demonstrable in the cervical and thoracic dorsal root ganglia at 32–40 months after infection and in the trigeminal ganglion at 36–38 months. Traces of infectivity were shown in sternal bone marrow in cattle killed 38 months post exposure. The earliest presence of abnormal PrP and infectivity in the CNS occurred 32 months post-exposure, prior to any typical diagnostic histopathological changes in the brain. The onset of clinical signs and pathological change in the brain occur at approximately the same time.

23.3.5

CLINICAL FINDINGS

The disease is insidious in onset and the clinical course progresses over several weeks, varying from 1 to 6 months in duration. There is a **constellation of clinical signs** with alterations in behavior, temperament, posture, sensorium and movement, but the clinical signs are variable from day to day although they are progressive over time Cattle that show behavioral, sensory and locomotor abnormality together are highly suspect for BSE.[7,50,55–58] The predominant **neurological signs** are apprehensive behavior, hyperesthesia and ataxia, and a high proportion of cases lose body condition and have a diminishing milk yield during the clinical course of the disease.

Clinical signs in BSE

- Change in temperament and behavior
  - apprehension, excitable, unusual kicking, head tossing when haltered, separation from group
- Change in posture and movement
  - abnormal posture and ataxia
- Fall in milk production

- **No ante-mortem test available**

Behavioral changes are gradual in onset and include changes, such as a reluctance to pass through the milking shed or to leave a vehicle or a pen, a change in milking order and a reluctance to pass through passageways. Affected cattle are disoriented and may stare, presumably at imaginary objects, for long periods. There is hyperesthesia to sound and touch, with twitching of the ears or more general muscle fasciculation and tremors. Many throw their head sideways and show head shaking when the head or neck is touched.

Other changes in **temperament** include the avoidance of other cows in loose housing, but antagonistic behavior to herdmates and humans when in confined situations. Affected animals may kick during milking and show resistance to handling. Some cows show excessive grooming and licking, and may show the equivalent of the scrapie scratch reflex.

Bradycardia, associated with increased vagal tone and not occurring due to decreased food intake is reported and may persist despite the cow's nervousness during clinical examination.[58,59]

Relatively early in the course of the disease there is **hindlimb ataxia** with a shortened stride, swaying gait, and difficulty in negotiating turns.

This should be especially examined as animals exit transport vehicles or are trotted through an area. Knuckling, stumbling and falling, with subsequent difficulty in rising is common in the later stages of the disease. Cows show **progressive weakness**, with ataxia and weight loss, and prior to the common recognition of the disease, they were sent to slaughter because of locomotor disabilities or changes in temperament.

It has been recommended[58] that the animals reaction to sudden noise, sudden light, sudden movement and sudden touch be used as a test. Sudden noise is tested by clanging two metal objects together out of sight of the animal – the bang test; sudden light by testing with a camera flash – the flash test; sudden movement tested by waving a clipboard towards the cow from a short distance – the clipboard test and sudden touch by touching the animal on the hind limbs a soft stick – stick test.

Abnormal reactions to theses tests include being startled, head tossing, salivation, snorting, running away or panicky circling and kicking out on touch. These tests have been found positive in BSE suspects that had a history of behavioral change but did not show abnormalities of gait.[58]

Cattle with BSE do not always show neurological signs in the initial stages of the disease and animals with BSE may be sent to slaughter for poor production prior to the onset of clinical nervous signs.[17]

1450
1451

23.3.5.1

Clinical signs and passive surveillance

There is yet no preclinical test for BSE and clinical recognition of BSE is the major component of passive surveillance.

At the peak of the outbreak in Britain, BSE was confirmed in 85% of suspects picked by passive surveillance. This percentage fell to 56% later in the outbreak. Farmers were fully compensated at notification and well informed and so were probably motivated to contact their veterinarian. Veterinarians were also very aware of the clinical presentation of BSE and observant at livestock markets and while TB testing and at abattoirs.[35] Relatively high success rates were also found in Switzerland where approximately 59% of animals notified with BSE were confirmed.[60,61] However, in other countries, passive surveillance was an utter failure.[15,62]

While an aid to surveillance of a disease, passive surveillance of BSE based on clinical signs is an insensitive method of disease detection and targeting surveillance of emergency slaughtered cattle and fallen stock is 40 times more likely to detect case of BSE than notification on the basis of clinical signs. One study found that the odds of finding a BSE case was 49 times higher in the fallen stock and 58 times higher in emergency slaughtered cattle greater than 24 months of age when compared with passive surveillance of clinical disease.[61]

23.3.6

CLINICAL PATHOLOGY

There is no specific test for the antemortem diagnosis of this disease. Apolipoprotein E and two unidentified proteins are present in the cerebrospinal fluid from clinical cases but not normal cattle, and the presence of a 30 kDa, 14–3–3 protein in cerebrospinal fluid in affected cows is reported, but there is no information of specificity.[63,64] Electroencephalographic and evoked potential diagnostic methods have been proposed as antemortem diagnostic test methods[65] but require further evaluation and would seem impractical.

23.3.7

NECROPSY FINDINGS

There are no abnormalities in gross pathology, and diagnosis is dependent upon histological findings.[66] Major changes are in the brain stem, and the pathognomonic lesion is a bilaterally symmetric intracytoplasmic vacuolation of neurons and gray matter neuropil. The occurrence of vacuolation in the solitary tract and the spinal tract of the trigeminal nerve in the medulla oblongata is the basis of statutory diagnosis of the disease in Great Britain. In Great Britain, statutory diagnosis is achieved by an examination of a single brain stem section obtained via the foramen magnum and obviating the need of extracting the brain with the associated risk of aerosol production.[28]

Histological findings are diagnostic in many cases but can be supplemented with the immunodetection of PrP^{Sc} in brain tissue by in situ immunohistochemistry and Western immunoblots.

There are a number of validated rapid tests for BSE.[67] Recently it has been established that the sensitivities of detection of BSE-specific PrP by immunohistochemistry and the detection of infectivity by mouse inoculation are equivalent and similar to the sensitivity of the rapid method (BSE Bio-Rad) for detection of PrP^{Sc}.[47,68]

Scrapie-associated fibrils can be visualized by electron microscopy. Government regulatory agencies are usually responsible for the confirmation of this diagnosis and typically distribute specific protocols regarding the collection of samples and disposal of carcasses from suspect animals.

23.3.7.1

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed brain, including midbrain and entire medulla oblongata (LM).

Note the zoonotic potential of this disease when handling carcass and submitting specimens.

23.3.7.1.1

DIFFERENTIAL DIAGNOSIS

The disease should be considered in the differential diagnosis of any progressive neurological disease in cattle. Primary differentials on clinical signs include:

- Hypomagnesemia
- Nervous acetonemia
- Rabies
- Lead poisoning
- Listeriosis
- Polioencephalomalacia
- Tremorogenic toxins.
- **Bovine amyloidotic spongiform encephalopathy.** In both Italy and France a form of spongiform encephalopathy different from BSE has been detected in brains collected as part of the active surveillance program in those countries. The cases were in older cattle and pathologically characterized by the presence of PrP-immunopositive amyloid plaques, as opposed to the lack of amyloid deposition in typical BSE cases, and by less involvement of the brainstem. There was some similarity to CJD in humans. There is no information on clinical presentation.[69] Other atypical forms have been reported in Belgium, and Japan.[70]

23.3.8 TREATMENT AND CONTROL

There is no treatment for the disease.

23.3.8.1 Detection of BSE in surveillance and control programs

Passive surveillance has been used in many countries. Suspect disease is notifiable with compulsory slaughter and compensation and disposal of the carcass by incineration. The limitations of passive surveillance are described above in the section on clinical findings and, in most countries, passive surveillance has been replaced with some form of active surveillance.

Commonly, **active surveillance** is directed at a targeted proportion of culled animals, animal manifesting neurological disease, rabies-suspects negative for rabies, and a proportion of cattle, or all cattle, over 24 to 30 months (depending on country) that are presented for slaughter for human consumption. In slaughter cattle, the sampling frame is

set to detect BSE at a prevalence rate of one mature animal in a million mature animals. The ability to conduct active surveillance, particularly on slaughter cattle, has been allowed by the development of rapid tests that can be conducted and read while the carcass is being held so that positive test cattle are not released for human consumption. Positive rapid tests need to be conformed by histology and immunohistochemistry.[15,71]

In the US, following the case of BSE in an imported cow, the USDA implemented an intensive national testing program for BSE that concentrated on a targeted high-risk population. The purpose is to help define if BSE is in the US and, if so, at what level. The intention is to sample as many cattle over a 12 to 18 month period as possible with the goal of examining 268 500 cattle which would allow a detection rate of 1 in 10 million with a 99% confidence level.[72] The cattle will be over 30 months-of-age and include non-ambulatory cattle, cattle that are too weak to walk, cattle that are moribund, cattle with neurological signs, rabies suspects that are negative and dead cattle. At the time of writing (2005) the survey is in currently in progress but has identified one native born BSE cow.

23.3.8.2

Control of BSE in cattle

Control programs have the following assumptions:

- Infection and disease in cattle is introduced through feeding contaminated feed containing infected meat-and-bone meal or greaves
- The source of infection to cattle can be eliminated by effective prohibition on feeding infected feed
- There is no significant horizontal or vertical transmission.

Based on this, most countries have established a ban on the feeding of ruminant protein to ruminants. This was done in the 1987 in the UK, the mid 1990s in most European countries and in 1997 in Canada, the US and Mexico. There is however a strong argument for banning all mammalian protein for feeding to all livestock. The experience of several countries with animals that were ‘born after the ban’ shows that cross contamination in feed mills can occur. While the removal of **specified-risk-materials** (SRM), (brain, spinal cord, eyes, tonsil, thymus, spleen, and intestines) from cattle carcasses should reduce the risk of BSE agent being in the subsequent rendered carcass it obviously does not eliminate it. More detail of the regulations and of control procedures is available.[15,28,71,73]

1451 1452

These control procedures, initiated in the UK, were effective in changing the course of their epidemic which is now on the wane.

23.3.8.3

Measures to protect human health

High risk animals, such as **downer cows**, should be kept out of the humans food chain and not rendered for meat-and-bone meal. Infection is present in the tissues listed as **SRM** (brain, spinal cord, eyes, tonsil, thymus, spleen, and intestines) which are removed from the carcass at slaughter. The removal of SRM also protects against the risk posed by cattle that may be incubating the disease yet do not show any symptoms. Together with a ban on products such as mechanically recovered meat that could be contaminated with SRM, excluding SRM from the human food chain is the most important food safety measure to protect public health.

However, this may not be sufficient. The method of slaughter with captive bolt guns can result in the widespread dissemination of brain within the carcass with dissemination by blood into the pulmonary tissues and elsewhere. Also, the method of splitting the carcass and spinal cord can result in significant carcass contamination and contamination of the slaughterhouse environment.[54] Methods to decease the risk of contamination of the carcass at slaughter have been suggested.[74]

Based on transmission and infectivity experiments cattle under 30 months of age[46–48] are considered to have very low risk of being infected but there can be a risk in endemic countries with cattle over this age. Some countries with a high incidence of BSE have banned cattle over 30 months for human consumption.

23.4 BSE AND SHEEP

There is considerable speculation and concern that the agent of BSE could have become established in small ruminants. BSE can be readily experimentally transmitted to sheep and goats and produces clinical signs and lesions similar to scrapie. There is further concern following a recent report of the transmission of the agent from challenged ewes to their lambs.[1] Further, the risk to human health from the ingestion of meat from sheep may be even greater than that from cattle because of the widespread distribution of the BSE agent in the lymphoid tissue of infected sheep.

In the UK and Europe concentrates are commonly fed to meat producing breeds of sheep in late pregnancy and early lactation and less commonly to their lambs. They are also fed to milk-producing sheep breeds and to lactating goats. Concentrates fed during the 1980s and 1990s could have contained infected meat-and-bone meal and this risk would have lasted until the total ban on feeding MBM to all farm animals in 1996 in the UK and 2001 in Europe.

The inclusion of meat-and-bone meal in concentrate rations for small ruminants was less than that for cattle and the proportion of concentrate ration fed was also lower. This, coupled with the fact that prion diseases require a larger infective dose to produce disease in a cross-species to that required to produce the disease in the same species, the **species barrier** effect, may have resulted in an infective dose to sheep was too low to establish infection.[2,3]

The possibility that BSE did establish in sheep during the BSE epidemic in Britain is not supported by a study that examined the incidence and new infection rates of scrapie flocks in Britain covering the period from 1962 to 1998.[2,4] This study found no evidence of a change in scrapie occurrence prior to, during, or following the BSE epidemic and no temporal or spatial correlations of scrapie occurrence with the BSE epidemic. There have been other studies that have examined the risk factors for transmission of BSE to sheep and the possibility that it could be perpetuated by sheep to sheep transmission. Most have concluded that the risk that BSE has established in sheep is low but, with current knowledge, cannot rule out the possibility.[2,3,5,6]

There are no reports of naturally occurring cases of BSE detected in sheep. However, there is a recent report of a transmissible spongiform encephalopathy in a goat in France that was found to have immunohistochemical and immunoblotting characteristics compatible with BSE, and,

following injection into mice, incubation times compatible with those recorded for experimental ovine BSE.[7]

23.4.1 Experimental transmission

BSE can be experimentally transmitted to sheep and goats by intracerebral, oral and intravenous routes using BSE-infected cow brain.[8–13] The PrP genotype affects the incubation period in both Cheviot and Romney sheep.[9,13] PrP genotypes ARQ/ARQ and AHQ/AHQ are associated with short incubation periods (approximately 18 to 36 months) following challenge and also with disease susceptibility. One study further suggests that AHQ/ARQ sheep have a similar susceptibility to infection and that sheep homozygous for alanine (A) at codon 131 and glutamine (Q) at codon 171 are more susceptible to BSE than any other genotype.[12] In contrast the PrP genotype ARR/ARR is associated with a long incubation period in sheep challenged intracerebally and ARR/ARR sheep are resistant to BSE challenged orally and do not have infectivity in their tissues.[6,11] The ARR allele appears dominant in this respect as sheep carrying at least one ARR allele in combination with any other allele have a longer incubation period.[9,10] PrP genotype VRQ/VRQ appears to have an intermediate incubation period.[12]

Texel and Lacaune sheep with PrP ARQ/ARQ genotypes are susceptible.[3] However, in these studies the survival of some sheep with susceptible genotypes suggests that factors other the PrP genotype has influence on survival. Challenge dose in all of these studies has been high.

In a recent study, 30 ewe lambs were dosed orally, at 6 months-of age, with 5 g of infected cattle brain and subsequently mated. Twenty-four developed clinical disease between 655 and 1065 days post-inoculation and two lambs, born before their dams had clinical disease, also subsequently developed clinical disease. This study indicated that the agent of BSE can transmit either in utero or perinatally in sheep. There is no information on other routes of transmission and if they exist.

23.4.2 PATHOGENESIS

Following challenge of sheep with BSE, infectivity has been found in intestinal Peyer's patches as early as 5 months post-infection and in enteric nerves and spinal cord after 10 months with widespread dissemination throughout the lymphoreticular system and peripheral nervous system by 21 months.[10]

23.4.3 CLINICAL SIGNS

The clinical signs reported in affected experimental animals are not well described in many of the experimental challenge studies but have varied in different studies. In one study, sheep and goats showed sudden onset of ataxia which progressed rapidly to recumbency. There was little evidence of pruritus and the clinical course was very short, lasting between 1 and 5 days in the majority of animals with one goat showing progressive weight loss over 3 weeks before it was culled. Genotype had no influence on the duration of the clinical course.[9] In another study in sheep only, the clinical course was approximately 3 months and affected sheep showed pruritus with fleece loss and ataxia and behavioral change.[8] Ataxia, weight loss, pruritus were considered constant in another.[13]

In an experiment designed to test specifically if clinical signs could be used for differentiation between scrapie and BSE two different groups of sheep were inoculated with each agent. The duration of clinical signs varied quite markedly within both groups with a mean of approximately nine days for each group but a variation in both from 1 to over 80 days. As with natural scrapie, there was considerable variation in the nature of the clinical signs, but there was no marked difference in the frequencies of clinical signs between the two groups, with exception that ataxia was the first sign noticed in a significantly greater proportion of the BSE-challenged group whereas pruritus was the first noticed sign in a significantly greater proportion of the scrapie-challenged group.[14]

23.4.4 DISPOSITION OF DISEASE-ASSOCIATED PrP

Genotype and route of inoculation influence the disposition of disease-associated PrP in lymphoreticular system tissues (tonsil, spleen, mesenteric lymph node). The most conspicuous effect is the absence of disease-associated PrP in peripheral lymph tissue in ARR/ARR genotype sheep and lack of infectivity[6,10–12] and there appears to be an inverse relation between this disposition and the incubation period. Route of inoculation influences the relative intensity of disposition in tonsil, spleen and mesenteric lymph node.

Following experimental infection of sheep with BSE, disease-associated PrP can be detected in tonsils biopsies 11 to 20 months after challenge but, in contrast to scrapie, disease-associated PrP is not detected in biopsies of lymphoid tissue from the third eyelid.[15]

23.4.5 DIAGNOSIS

The diagnosis of BSE in clinically affected cattle can be achieved with several techniques, including the analysis of symptoms, histopathology and the detection of the disease-associated form of the prion protein, by immunocytochemistry, western blot or ELISA. The profiling of vacuoles in affected host had shown a remarkable uniformity over the year and from different geographic regions.[16,17] However this is not true with scrapie and the variation in the host brain with scrapie would not allow differentiation from BSE on histological findings. The diagnosis of BSE in sheep presents problems and the similarity of the clinical signs and pathology between scrapie and BSE could easily result in naturally occurring cases of BSE in sheep being misdiagnosed as scrapie.

23.4.5.1 Strain tying

The 'gold-standard' technique for the diagnosis of TSE agents is the passage of tissue in panels of inbred mice, a technique known as 'strain typing'.[18] Until recently this was the only way to differentiate the two diseases. BSE presents with a characteristic range of incubation periods and a pattern of distribution and relative severity of changes in the brain of the different mouse strains – the lesion profile – which is distinct from all scrapie strains tested to date. However, this method of diagnosis is both expensive and time consuming.

There has been a wide search for a differential test system in including prion protein profiling, studies in glycosylation and glycoform ratios and other molecular and biochemical studies that are detailed elsewhere.[3] A recent promising set of studies suggests that the site of truncation of disease-associated PrP during partial digestion by proteases located in lysozymes, appears different for sheep scrapie and experimental BSE. After digestion by exogenous enzymes, the BSE PrP molecule is shorter than that of scrapie 1453
stains giving rise to different immunohistochemical patterns[19] and this is supported by 1454
western blot studies.[20] Unlike scrapie, the intracellular truncation site of ovine BSE PrP is influenced by the cell type in which it accumulates giving distinct patterns of immunolabeling with different PrP antibodies. Epitope labeling shows that the shortest fragment of diseases-associated PrP occurs in tangible body macrophages followed glial cells and neurons. It appears that this difference in truncation of PrP in experimentally infected BSE sheep is not influenced by route of inoculation or by genotype or by sheep bred, and it is proposed that truncation patterns, as detected by immunoblotting and immunohistochemistry, can be used in surveys for BSE in sheep.[12,21]

23.4.6

CONTROL

If BSE is or does establish in small ruminants in a country there is a significant concern for human health. The distribution of BSE infection in the carcasses of cattle is limited and can be removed by the ban of the use of specified risk materials (largely brain spinal cord and offals). In contrast, the distribution of the BSE agent in infected sheep is widespread and it would be virtually impossible to remove this by trimming or selective organ removal from a carcass for human consumption. Also lymphocytes in milk could be infected.

In the UK, a worst case scenario, published in 2001 in a contingency plan to address BSE in sheep, threatened the national herd with slaughter, largely on the grounds that an epidemic of BSE in sheep could be harder to contain than was the case for BSE in cattle, and that lamb could present a greater risk to consumers than beef. A more recent UK contingency plan[22] would allow PrP genotype ARR homozygous sheep and ARR heterozygous sheep for human consumption. This plan is the same as the EU, except that there are differ-ences in the maximum age allowed at slaughter between the UK and the EU recommendations.

The risk for BSE in sheep was a major incentive for the development of national breeding programs for the control of scrapie, and possible BSE, including the National Scrapie Plan in the UK, launched in 2001, and the National Scrapie Eradication Program in the US. The purpose in these breeding programs is to select against highly susceptible genotypes and select for the highly resistant genotype.

23.5 CHRONIC WASTING DISEASE

Chronic wasting disease (CWD) has recently emerged, or been recognized, in the USA as a transmissible spongiform encephalopathy of captive and free-ranging cervids. The ability of this infection to transmit laterally between cervids, coupled with the longevity of the agent in the environment and the common grazing land of infected cervids and cattle and sheep have resulted in concern that CWD in cervids might be a risk to livestock, and subsequently to humans, similar to bovine spongiform encephalopathy. There has also been concern that it might be transmitted directly from infected cervids to hunters dressing carcasses or consuming deer meat. To date there is no evidence for either of these risks.

The known natural hosts for CWD are mule deer (*Odocoileus hemionus*), white-tailed deer (*Odocoileus virginianus*) and Rocky Mountain elk (*Cervus elaphus nelsoni*). CWD was originally recorded in the late 1960s as a chronic wasting syndrome of unknown etiology in captive mule deer in research facilities in Colorado and Wyoming.[1,2] It was subsequently established that the disease was a transmissible spongiform encephalopathy and CWD has subsequently been found affecting cervids in captivity in several states in the USA and also in the provinces of Saskatchewan and Alberta in Canada. The occurrence in captive and farmed cervids in these different geographical areas is likely the result of transfer of animals between

them,[2] and the disease has recently been reported in Korea in cervids imported from North America.[3]

The disease has a focus, and may have originated, in free ranging deer and elk in north-central Colorado and southeastern Wyoming[4] however, in recent years it has been detected in free ranging cervids east of the Mississippi and in a much broader area of North America. It is not certain if this is due to spread or because of improved surveillance. Based on comparisons of the central nervous system lesions and the glycoform patterns, the CWD agent is the same in captive and free-ranging deer.[5]

There is strong evidence from outbreaks in captive deer that lateral transmission is of major importance in the transmission of CWD.[6] The agent accumulates in gut-associated lymphoid tissues early in the infection and saliva and feces are the likely source of infection with contamination of the environment.

The disease can be transmitted experimentally between cervids and there is evidence for genetic susceptibility.[7,8] The prion associated with CWD is not the same as that associated with BSE.[9] In a recent study, it was shown that infection, with amplification of prion protein in brain tissue, can be transmitted to cattle by intracerebral inoculation of CWD-infected deer brain. Six years following challenge less than 50% of the challenged cattle showed amplification of the infection and none had histological evidence of spongiform encephalopathy.[10] It was concluded that if infection via the oral route did occur in cattle it would be unlikely that it would result in amplification of the abnormal prion within the lifespan of cattle.

Clinically the disease in cervids is manifest initially by changes in behavior, not commonly observed in free-ranging cervids, with the major manifestation being a marked fall in body condition. In the terminal stages there may be ataxia and excitability. The clinical course varies from a few days to a year but averages 4 months.[2] Diagnosis is by histological examination of the brain or more commonly by the demonstration of PrP^{CWD} in brain tissue by immunohistochemistry.

24 Chapter 24 Diseases associated with Rickettsiales

24.1 ANAPLASMOSIS

24.1.1 Synopsis

24.1.1.1 Etiology

Anaplasma marginale in cattle and wild ruminants, and *A. ovis* in sheep and goats. *A. centrale* causes mild anaplasmosis in cattle

24.1.1.2 Epidemiology

Common in tropical and sub-tropical regions; sporadic in temperate regions. Carrier animals are the source of infection. Disease transmitted by ticks, mechanically by tabanid vectors, iatrogenically, and transplacentally. Disease can be endemic in tick areas or sporadic in interface regions between endemic and free areas

24.1.1.3 Clinical findings

In cattle death or severe debility, emaciation, anemia and jaundice are the major clinical signs. The disease is usually subclinical in sheep and goats

24.1.1.4 Clinical pathology

Anemia, demonstration of organism in red cells by microscopy, fluorescent stains or PCR, serology

24.1.1.5 Necropsy findings

Anemia and attendant findings. Demonstration of organism

24.1.1.6 Diagnostic confirmation

Detection of the organism in blood smears, positive serology, PCR, and in some circumstances positive transmission tests. The sensitivity, in a group of animals, can be increased by using parallel blood smears and serological tests

24.1.1.7

Treatment

Clinical cases treated with tetracycline or imidocarb. Blood transfusion. Carrier state cannot be eliminated by treatment with tetracycline

24.1.1.8

Control

Tetracycline provides temporary or prolonged protection in face of an outbreak. Vaccination with killed *A. marginale* vaccine or live *A. centrale* vaccine used in endemic areas as is weekly dipping in acaricides. In non-endemic areas, serological identification of carriers and culling or treatment of reactors. Prevention of iatrogenic transmission

24.1.2

ETIOLOGY

Anaplasma spp. are obligate intra-erythrocytic parasites belonging to the order Rickettsiales and infecting ruminants. Analyses of 16S rRNA, groESL, and surface proteins have resulted in reclassification of the order Rickettsiales. The genus *Anaplasma*, of which *A. marginale* is the type species, now also includes *A. bovis*, *A. platys*, and *A. phagocytophilum*, which were previously known as *Ehrlichia bovis*, *E. platys*, and *E. phagocytophila*.[1]

Anaplasma marginale is the causative agent of anaplasmosis in cattle and wild ruminants, and *A. ovis* in sheep and goats. *A. centrale* is closely related to *A. marginale* and causes mild anaplasmosis in cattle. It was originally isolated in Africa but has been introduced as an immunizing agent in Australia, South America and Asia. There are antigenic variants among isolates of *A. marginale*, the six major surface protein antigens being antigenically polymorphic.[1,2]

24.1.3

EPIDEMIOLOGY

24.1.3.1

Geographic occurrence

Anaplasmosis in cattle is common on **all six continents**, being present in South Africa, Australia, Asia, the former USSR, South America and the United States. It is transmitted by a diverse group of biological and mechanical vectors. Infection in cattle is **endemic** in tropical and subtropical areas that support large populations of these vectors. Infection occurs more **sporadically** in temperate climate areas.

In the United States, and in other countries, the disease has occurred beyond the boundaries of tick-infested areas and the area distribution in **Europe** has been advancing northward in recent years with sporadic cases in France, Switzerland, the Netherlands, Hungary, and Austria.[3] Anaplasmosis of sheep and goats has a distribution similar to that of cattle.

In the **USA** anaplasmosis is enzootic throughout the southern Atlantic states, the Gulf Coast states and many of the midwestern and western states.[3,4] Disease occurs sporadically in the northern states and Canada.

In **Australia** infection is closely related to the distribution of *Boophilus microplus*, which is restricted to the northern areas. Seropositivity is negligible in cattle south of the tick line but above the tick line increases from south to north. Differences in enzootic and epizootic areas in South America and South Africa are also largely related to tick distribution and climate.

In most countries there is wide geographical variation in seroprevalence and this variability contributes to the development of geographically stable or unstable enzootic regions.

There is concern, and some evidence, that the global warming trend will expand the boundaries and movement of host ticks.[1]

24.1.3.2

Host occurrence

Cattle are susceptible to *A. marginale* and *A. centrale* and sheep to *A. ovis*. *A. marginale* will establish in sheep by experimental infection but *A. ovis* will not infect cattle.[5] A variety of species of **wild ruminants** in both North America and Africa can be infected and may have significance as reservoirs for *A. marginale*.[6,7] In the United States the black-tail deer (*Odocoileus hemionus columbianus*) in the West Coast region is believed a reservoir and a number of species of antelope play a similar role in South Africa. Bighorn sheep (*Ovis canadensis*) may be a reservoir for *A. ovis* in the western United States.[8]

The prevalence of infection in cattle in endemic areas is very high with seropositivity rates exceeding 60% and often approaching 90%. Seropositivity is much lower in regions that interface between endemic and non-endemic regions.[9]

24.1.3.3

Source and methods of transmission

The source of infection is always the blood of an infected animal. Recovery from acute infection results in **persistent infection** characterized by repetitive cycles of rickettsemia. Persistent carriers are the reservoir for herd infection. The level of parasitemia is often too low for detection by microscopy but can be detected by nucleic acid probe analysis.[10] Transmission is biologically by ticks but can also occur transplacental and can also be effected mechanically by biting flies or blood-contaminated fomites.

24.1.3.3.1

Hematophagous insect transmission

Spread from animal to animal occurs chiefly by insect vectors. A variety of arthropods may act as vectors but significant natural vectors are ticks in the **family Ixodidae** and flies in the **family Tabanidae**. Of the ticks, the one-host ***Boophilus* spp.** are of major importance in tropical and sub-tropical regions and the three-host **Dermacentor spp.** of major importance in the western US.

1455

1456

The organism undergoes a complex developmental cycle in the gut cells of ticks and the final infective stage is present in the salivary gland.[11] **Trans-stadial** transmission of the organism occurs in ticks but there is little evidence for transovarial transmission. **Intrastadial** transmission is significant with some species and transmission occurs as the ticks move from one host to another while they are engorging, including from cow to calf. Male *D. andersoni* can act as effective vectors in this manner for at least 120 days.[12]

There appears to be no developmental sequence of *Anaplasma* spp. in flying insects. **Tabanids** are efficient mechanical vectors and can transmit infection for 2 hours after feeding.

Over 20 species of tick have been incriminated as vectors world-wide.[13] In **Australia** the ticks *Boophilus microplus* and *Rhipicephalus sanguineus*[14] are the vectors and in **South Africa** it is *B. microplus*, *B. decoloratus*, and *Rhipicephalus simus*. In the **United States** *Boophilus annulatus*, *Dermacentor andersoni*, *D. variabilis*, *Argas persicus* and biting flies of tabanid species and eye gnats (*Hippelates pusio*)[15,16] also act as vectors. The male ticks of *Dermacentor albipictus* (the winter tick) and *D. occidentalis* (the Pacific Coast tick) parasitize both deer and cattle and have been suspected as vectors.[17]

24.1.3.3.2

Iatrogenic transmission

Anaplasmosis may also be spread mechanically by infected **hypodermic needles**, by castrating, spaying and dehorning **instruments**, and by **blood transfusions** and embryo transplants. The ease with which the infection is spread mechanically may vary with the virulence of the protozoan strain and this method of spread may be more important in some countries than others. Anaplasmosis may also be spread when cattle, used as donors of infected blood for immunization against babesiosis, are infected with *A. marginale*, the reaction occurring some 3 weeks later than that due to the babesia.

24.1.3.3.3

Transplacental transmission

Intra-uterine infection also occurs in **cattle** but much less frequently in field cases than in experimental ones.[18] Abortion or neonatal infection may result. In **ewes** intra-uterine infection appears to occur with ease in experimental cases provided the ewe is exposed during the latter two-thirds of pregnancy.[19]

24.1.3.4

Animal and environmental risk factors

24.1.3.4.1

Breed

Bos indicus, *Bos taurus* and their crosses have **equal susceptibility** to infection and show the same age susceptibility, but under field conditions *Bos indicus* are not as commonly affected, probably because of their relative resistance to heavy tick infestation. However, the effects of the disease on body weight and clinicopathological parameters are the same for the two races of cattle.[20] Breeds with black or red **coat color** have a higher risk of infection than those with white coats in regions where biting flies are the insect vector.[4,9] Dairy breeds may be at greater risk for iatrogenic transmission.

24.1.3.4.2

Nutritional status

Clinical disease is less severe in cattle on a low plane of nutrition. Exposure of infected, clinically normal animals to devitalizing environmental influences, particularly shortage of feed, and the presence of other diseases, may result in the development of acute anaplasmosis. For example, cattle introduced into feedlots are highly susceptible and outbreaks among them are not uncommon 2–3 weeks after entry.

24.1.3.4.3

Season

In temperate climates a seasonal occurrence of disease occurs in association with seasonal occurrence of the insect vectors.[4,16,21,22] Winter outbreaks are likely associated with iatrogenic transmission[9] or possibly the winter tick, *D. albipictus*.[16]

24.1.3.4.4

Age at infection

All cattle are susceptible to infection but age at infection is a **major determinant** of the severity of clinical disease. Young calves are less susceptible to infection with *A. marginale* than older cattle and, when infected, are less susceptible to clinical disease. The reason for, this is not understood but splenectomized calves are fully susceptible to infection, which may be more severe than in the adult. Infection between six months and three years of age has increasing risk of clinical illness and animals infected **after 3 years** of age are commonly affected by a peracute fatal form of the disease. The **age-specific incidence** of clinical disease recorded in an outbreak in the USA showed 81% of cases in cattle aged between 2–4 years with 94% of cases in cattle 3 years of age or older.[4]

24.1.3.4.5

Geographic region

Clinical disease is rare in **enzootic areas** because the infection pressure is high and cattle are infected at an age when they are age-resistant to clinical disease. The average age at which calves in enzootic areas become infected is 11 (4–24) weeks and the clinical and hematological changes in them are mild and brief. Animals in an infected environment which have become seronegative for whatever reason are fully susceptible to infection.[23] Clinical disease occurs where there is **introduction** of susceptible animals into endemic areas or the **expansion** of the vector population into previously free areas or into the **interface** between endemic and non-endemic regions.

Case fatality rates are usually high in outbreaks but the mortality rate varies widely depending on susceptibility, and may be 50% or more in cattle introduced to enzootic areas. Case fatality rates of 29–49% are recorded in outbreaks in the USA; recovered animals are emaciated and there is a prolonged convalescence.[4]

24.1.3.5

Pathogen risk factors

Phylogenetic analysis of *A. marginale* geographic isolates support the existence of clades.[1] Australian isolates do not appear to differ significantly in antigenicity or virulence.[24] In contrast in other countries there can be significant differences between isolates in antigenic composition, the protection afforded against heterologous challenge and virulence.[25–29]

Recent research has demonstrated that the phenomenon of infection exclusion occurs with *A. marginale*. Infection of tick cells and bovine erythrocytes with one genotype of *Anaplasma marginale* excluded infection with other genotypes and in herds of cattle from endemic areas where many genotypes were detected only one genotype was found per animal. Further cattle inoculated with two *A. marginale* isolates became infected with only one isolate.[28,29]

24.1.3.6

Economic importance

Costs are from death and abortion in clinical cases, loss of production in sick and recovered animals, and costs associated with preventive measures such as tick control. There have been few recent estimates of cost, the most recent estimates in 1977 and were of a cost of $875 millions in Latin American nations.[30]

In developed countries with the disease exports of cattle to countries that do not have it are constrained. A major cost in developing countries is the constraint to efficient production and the limit to the introduction of susceptible cattle breeds with superior genetics.[4,31]

24.1.4

PATHOGENESIS

Anaplasma are obligate intra-erythrocytic bacteria. They infect **mature erythrocytes** by an endocytic process and reproduction occurs by binary fission to produce 2–8 infective initial bodies which leave by exocytosis to infect other erythrocytes. The number of infected erythrocytes doubles every 24–48 hours and the infection becomes patent 2–6 weeks after infection,[32] the time influenced by the initial challenge dose.[33] Depending upon the strain and the susceptibility of the host, from 10–90% of erythrocytes may be parasitized in the acute stage of the infection. At least 15% have to be parasitized before there is clinical disease. Parasitized erythrocytes are removed by phagocytosis in the reticular endothelial system, with release of acute-phase inflammatory reactants and the consequent development

1456
1457

of fever. Continued erythrocyte destruction occurs resulting in the development of mild to severe anemia and icterus without hemoglobinemia and hemoglobinuria. Anaplasmosis is primarily an **anemia**, the degree of anemia varying with the proportion of erythrocytes which are parasitized. The first appearance of the protozoa in the blood coincides with a fall in the hematocrit and erythrocyte levels, the appearance of immature erythrocytes in blood smears and the development of fever. Acutely affected animals may die shortly after this phase is reached. The appearance of anti-erythrocyte antibodies late in the acute stage may exacerbate the anemia.[32]

If the animal recovers from the initial acute attack, periodic attacks of parasitic invasion of mature erythrocytes occur regularly, but with diminishing intensity. The degree of anemia varies widely in young cattle up to 3 years of age but is always severe in adults and in splenectomized animals. Cattle that survive the disease become carriers and serve as reservoirs of *A. marginale* because they provide a source of infective blood for both mechanical and biological transmission by ticks. They have lifelong immunity and are resistant to clinical disease on challenge exposure.

Carrier animals have **cycles of parasitemia**, possibly associated with the development of new antigenic variants to allow new cycles of invasion and multiplication.[34] These occur at approximate 5-week intervals during which the new variants replicate and are then controlled by a variant-specific immune response.

24.1.5 CLINICAL FINDINGS

24.1.5.1 Cattle

In cattle, the **incubation period** varies with the challenge dose but is generally about 3–4 weeks with tick-borne infection and 2–5 weeks with the inoculation of blood. In most cases the disease is subacute, especially in young animals. **Rectal temperature** rises rather slowly and rarely to above 40.5°C (105°F). It may remain elevated or fluctuate with irregular periods of fever and normal temperature alternating for several days to 2 weeks. Anorexia is seldom complete. **Death** can occur at this stage but many **survive in an emaciated condition**, and their fertility is impaired. The mucous membranes are jaundiced and show marked pallor, particularly after the acute stage is passed, but there is **no hemoglobinuria**.

Peracute cases, with a sudden onset of high fever, anemia, icterus, severe dyspnea and death, often within 24 hours, are not uncommon in adult dairy cows. Affected animals are

often **hyperexcitable** and tend to attack attendants just before death. Pregnant cows frequently abort. In convalescent bulls there may be depressed testicular function for several months.

24.1.5.2 ## Sheep and goats

In sheep and goats, infection is usually *subclinical* but in some cases, particularly in goats, a severe anemia may occur and a clinical picture similar to that found in cattle may be seen. Severe reactions of this type in goats are most frequent when the animals are suffering from concurrent disease. Goats may show hyperexcitability and may bite at inanimate objects. The experimental disease in lambs includes fever, constipation or diarrhea, pale, icteric conjunctivae and severe anemia 15–20 days after inoculation. The anemia is not completely resolved in 3–4 months.

24.1.6 # CLINICAL PATHOLOGY

24.1.6.1 ## Hematology

Erythrocyte destruction may be so severe that the erythrocyte count is reduced to 1.5 million/μL. Immature red cells are common at this stage and their presence is considered to be a favorable sign. The small dot-like protozoa are discernible at the periphery of up to 10% of the red cells in subacute cases, but in peracute cases more than 50% of the cells may be parasitized. *A. ovis* are usually situated at the periphery of erythrocytes but as many as 40% of infested cells may show submarginal protozoa. Diff-Quik staining of blood smears is as accurate as Giemsa in the detection of *A. marginale* and can be completed in 15 seconds as compared to nearly an hour[35] for Giemsa. There are no diagnostic clinical chemistry findings.

24.1.6.1.1 ### Serology

The complement fixation test is the standard test for the detection of carrier animals. It is satisfactory for use in cattle, goats and sheep but the antibody titer is highest during the active phase of the disease and sufficiently low in carrier animals to give a proportion of false negative results. False positive reactions can occur because of erythrocyte contamination of the *A. marginale* antigen and the presence of antibodies to erythrocytes in some cattle sera. A rapid card agglutination test, which tests serum or plasma for antibodies against *A. marginale*, is cheap and quick, and sufficiently accurate to be used

as a herd test. Currently, in most countries, the card agglutination and complement fixation tests are routinely available.

There are a number of other tests that have been developed. A capillary tube agglutination test of comparable efficiency is available, is more economical and faster than the CF test[36] and is particularly suited to testing in extensive field situations. An indirect fluorescent antibody test is also accurate[37] and has a particularly suitability for testing blood which has been dried onto paper for passage through the mails. It is also an accurate test for selecting recently affected animals. A dot-ELISA with high sensitivity, specificity and predictive value is also described and could be particularly applicable to field examinations.[10,38] A competitive inhibition ELISA test, with high sensitivity and specificity, has been developed that detects antibody to a major surface protein that is conserved among anaplasma species; this test can be used to detect cattle persistently infected for as long as six years.[39–41] Vaccinated animals may react to all of the serological tests for periods of over one year.

24.1.6.2

Other methods

Nucleic probe analysis can be used to detect low levels of parasitemia.[10,42–44] **Transmission** to splenectomized animals has been used to detect carriers but is expensive and is now replaced by PCR in countries where this technology is available.

24.1.7

NECROPSY FINDINGS

The most obvious findings are emaciation, pallor of the tissues, and thin, watery blood. There is mild jaundice and the liver is enlarged and orange. The kidneys are congested and there may be myocardial hemorrhages. The spleen is enlarged with a soft pulp. The bone marrow cavity may be reddened by increased hematopoietic tissue in acute cases but there may be serous atrophy of marrow fat in chronic cases. Postmortem identification of *A. marginale* can be established by staining blood smears with Giemsa or direct fluorescent stains. Peripheral blood is superior to organ smears. Brain smears are unsatisfactory. The technique is applicable to fetuses suspected of being aborted as a result of infection with *Anaplasma* sp. Nucleic acid-based tests may be used but are rarely needed for routine diagnosis at necropsy.

24.1.7.1 Samples for confirmation of diagnosis

- **Clinical pathology** – blood smears from cut surface of an ear (CYTO, FAT)
- **Histology** – fixed spleen, liver, bone marrow.

24.1.7.1.1 DIFFERENTIAL DIAGNOSIS

Other causes of hemolytic anemia.

1457

1458

24.1.8 TREATMENT

Treatment is with **tetracyclines**. Treatment of **clinical disease** can be with oxytetracycline, 6–10 mg/kg BW daily for three days, or a single injection of long-acting oxytetracycline at a dose of 20 mg/kg intramuscularly. The convalescent period is long. Concurrent administration of **estradiol** cypionate (14.3 mg/kg BW intramuscularly) appears to improve the rate of recovery by promoting parasitemia during treatment.[45] Tetracycline treatment will not eliminate infection and immunity will persist.[32] **Blood transfusions** are indicated in animals with a PCV less than 15%. Rough handling must be avoided.

Imidocarb (3 mg/kg BW) is also an effective treatment for clinical cases and does not interfere with the development of acquired immunity to *A. marginale*.[46]

The risk for infection in the rest of the herd should be assessed and, if necessary, temporary or prolonged protection should be provided. Protection can be provided by tetracyclines, or by vaccination.

Temporary protection in the face of an exposure risk can be achieved with a single intramuscular injection at 20 mg/kg BW of long-acting tetracycline.[32] The results generally are good except when the cattle are exposed to infection during the 14 days prior to the treatment. **Prolonged protection** can be achieved by the intramuscular injection at 20 mg/kg BW of long-acting tetracycline every 28 days or by chlortetracycline in the feed at 1.1 mg/kg BW daily.[32]

Elimination of infection cannot be achieved with tetracycline therapy. A trial testing the ability of oxytetracycline therapy to eliminate the carrier state examined therapy with 300 mg/mL oxtetracycline solution of administered at 30 mg/kg, by intramuscular (IM) injection for one day; the same preparation administered at 30 mg/kg, IM on day 0 and again on day 5;

and a treatment with a 200 mg/mL solution of oxytetracycline administered at 22 mg/kg, intravenously (IV), q 24 h for 5 days (a treatment dose that corresponds with current Office International des Epizooties (OIE) recommendations for treatment prior to export). All treated cattle were still, PCR and cELISA positive 60 days after therapy and their carrier status was confirmed by inoculation of blood in splenectomized calves.[47]

24.1.9 ## CONTROL

Methods for the control of anaplasmosis have not changed greatly over the past several decades and consist of arthropod control with acaricides, chemotherapy for prevention and vaccination. The eradication of anaplasmosis is not a practicable procedure in most countries at the present time because of the wide range of insects which are capable of carrying the disease, the long period of infectivity of carrier animals, and, in some areas, the presence of carriers in the wild animal population. In enzootic areas some benefit is derived from the control of ticks and other vectors and weekly dipping in an **acaricide** is used in tropical areas to control this and other tick-borne diseases.

24.1.9.1 ### General measures

The introduction of the disease into herds by carrier animals should be prevented by prior **serological testing**. Attention should also be given to preventing **iatrogenic transmission** with instruments used for injections or surgical operations by disinfection after use on each animal. This is particularly important in feedlots where introduced groups are often subjected to multiple vaccinations and implantation at a time when their resistance is lowered by transport and change of feed.

24.1.9.2 ### Movement of animals

Exposure-naive animals that are to be introduced into an enzootic area should be vaccinated. Some advantage can be gained when introducing animals into an enzootic area by limiting the introductions to animals of less than 2 years of age and by bringing them in when the insect population is least numerous.

24.1.9.3 ### Elimination of carriers

This is feasible in regions that are subject to only periodic incursions of infection and that do not have endemic tick vectors. It can be achieved by serologic testing and **culling of reactors** or treating them as outlined above to eliminate the carrier state.

24.1.9.4

Outbreaks

If an outbreak does occur, affected animals should be treated vigorously as described above and in-contact animals vaccinated and/or placed on a regimen of prolonged tetracycline protection. Subsequently all exposed animals should be tested serologically and the reactors treated or preferably salvaged. Prolonged treatment regimens can be used to provide protection to cattle in seasonal risk periods of transmission.

24.1.9.5

Chemotherapy

Chemotherapy for control is more commonly used in the United States than in other areas of the world. It can be of value in feedlot cattle but is not applicable to range cattle. It is expensive and carries the risk of causing selection of resistant strains.[1]

24.1.9.6

Vaccination

Vaccines for the control of anaplasmosis are either live or killed vaccines. Both types use *A. marginale* from infected bovine erythrocytes and while both types induce protective immunity that reduces or prevents clinical disease neither type prevents cattle from becoming persistently infected with *A. marginale*. Cattle that have recovered from acute infection or immunized with killed vaccines are solidly protected against challenge with the homologous strain but are only partially protected against challenge with heterologous strains.[48]

Most control programs in enzootic areas are based on increasing the resistance of the population by immunization. In any vaccination program particular attention should be paid to the **animals at high risk**, particularly animals brought in from non-enzootic areas, those in surrounding similar areas to which infection may be spread by expansion of the vector population under the influence of suitable climatic conditions, and animals within the area which are likely to be exposed to climatic or nutritional stress.

24.1.9.6.1

Killed vaccines

Killed *A. marginale* are usually in an adjuvant vehicle. The vaccine requires two doses, four weeks apart, the last dose given at least two weeks before the vector season. Subsequently, **booster** doses should be given two weeks before the next vector season. The vaccine does not prevent infection but does significantly **reduce the severity** of the

disease. It does have the advantage over the other vaccines of having a relatively short post-vaccination period when animals remain positive to serological tests. The duration of the immunity is at least 5 months.

There is a risk for **neonatal isoerythrolysis**. This can be reduced by vaccinating only empty cows and avoiding unnecessary booster injections. When this vaccine is used in the face of an outbreak, tetracyclines can also be given to provide temporary protection during the period of development of immunity; tetracyclines do not interfere with the development of this immunity.

Preliminary reports of the efficacy of DNA vaccines are not encouraging.[49]

24.1.9.6.2

Live vaccines

A living A. centrale vaccine is used extensively in Australia, Africa, Israel, and Latin America, but not in the United States and there is some reluctance to introduce it into areas where *A. centrale* does not already occur.

Living *A. centrale* vaccine is prepared from the blood of infected splenectomized donor calves and is stored chilled or frozen. The vaccine causes a mild, inapparent disease, but does cause severe reactions in occasional animals. It is generally safe in young cattle. A **single vaccination** is used in endemic areas and the immunity is reinforced by continuous challenge and considered to persist for life in tick areas. *A. centrale* and *A. marginale* share immunodominant epitopes and have similar antigenic variation in major surface proteins which may play a role in the cross immunity that occurs.[50,51] It is unclear whether *A. centrale* infection and immunity induced by the live vaccine in cattle prevents subsequent infection with *A. marginale* by the infection exclusion phenomenon.[28,29,51]

1458

1459

The efficacy of this vaccine varies geographically.[52] Vaccination with *A. centrale* reduces the severity of the reaction when infection with *A. marginale* occurs but does not give absolute protection. Protection against challenge in Australia is adequate in most cases, and certainly sufficiently effective enough to justify its use. In contrast the use of the same vaccine in countries other than Australia, where there are more antigenically diverse and highly virulent strains is often inadequate and better vaccines are required.[52]

Tetracyclines will prevent establishment of infection and immunity by the vaccine and should not be administered for 3 weeks before vaccination.

Living *A. marginale* has been used as a vaccine but its administration is limited to the relatively resistant age group below 1 year of age, to the winter months when vectors are sufficiently rare to avoid the chance of spread to other age groups, and to circumstances where animals which react severely can be restrained and treated adequately. The method has the serious disadvantage of creating a large population of carrier animals which may subsequently spread the disease.[53]

Attenuated vaccines have been attempted by irradiation of strains and passage of the organism through sheep or deer and the use of naturally low virulence isolates. While most have been received with initial enthusiasm some have proved not effective while others have been associated with adverse reactions. Some, while effective against strains in some geographic regions, give unsatisfactory protection against clinical disease in other regions.[54–56]

24.1.9.6.3

Problems with live vaccines

All vaccines currently must be produced in live animals, which is expensive. With non-inactivated vaccines there is a risk of transmitting blood-borne viruses. In Australia, a single calf infected with bovine leukosis virus was unsuspectingly used in the production of *A. centrale* vaccine. The contaminated vaccine was given to 22 627 cattle in 111 herds and resulted in a high rate of infection with bovine leukosis virus in the vaccinated cattle.[14]

It is highly probable that a safe **subunit vaccine**, containing epitopes critical to effective immunity, will be developed in the near future.

24.2 ## TICK-BORNE FEVER

24.2.1 ### Synopsis

24.2.1.1 #### Etiology

Anaplasma phagocytophila

24.2.1.2 #### Epidemiology

Occurs in the northern latitudes and is transmitted by *Ixodes ricinus* in UK and Europe and *Ixodes scapularis* and *Ixodes pacificus* in the USA. Disease in cattle and sheep primarily reported from the UK and Europe. Seasonal occurrence associated with the feeding activity of the vector. More severe disease in naive introduced animals. Increases susceptibility to other infections

24.2.1.3 #### Clinical findings

Fever, depression, lethargy, polypnea and fall in milk production in cattle. Abortion

24.2.1.4 #### Clinical pathology

Thrombocytopenia followed by more prolonged neutropenia and lymphocytopenia. The organism is demonstrable in the neutrophils and monocytes during each febrile period

24.2.1.5 #### Diagnostic confirmation

Demonstration of the *E. phagocytophila* in leukocytes at acute stage of the disease or by serology retrospectively

24.2.1.6 Treatment

Oxytetracycline

24.2.1.7 Control

Oxytetracycline during risk period. Tick control

24.2.2 ETIOLOGY

Tick-borne fever (also called pasture fever in cattle) is associated with infection with *Anaplasma phagocytophila*, (*Ehrlichia phagocytophila*, *Cytoecetes phagocytophila*) which is an obligate intracellular parasite in the family *Anaplasmataceae*. *Anaplasma phagocytophila* and the human granulocytic ehrlichial agent (HGE) and *Ehrlichia equi* are morphologically identical, they have only minor variations in their 16S rRNA genes and 100% identity in their GroESL amino acid sequences, and so are now all classified as *Anaplasma phagocytophila*.

There are strains (variants) of *A. phagocytophila* that have biological and ecological differences, including variations in host pathogenicity, vectors, and geographical distribution.[1,2] In sheep, different variants of *A. phagocytophilum* may exist simultaneously in the same sheep flock.[3]

Tick-borne fever is also used as a name for similar, but less well defined, diseases of ruminants that are associated with infection with related organisms such as *Anaplasma* (*Ehrlichia*) *bovis*. These are reported from other areas of the world such as India and Africa, and are transmitted by the ticks *Rhipicephalus appendiculatus*, *Amblyomma variegatum* and *Hyalomma truncatum*.[4,5]

This description is of tick-borne fever associated with *A. phagocytophila*.

24.2.3 EPIDEMIOLOGY

24.2.3.1 Occurrence

Infection with *A. phagocytophilum* occurs in a wide range of mammalian hosts including humans, dogs, sheep, cows, horses, wild deer and rodents. The association of *A. phagocytophilum* with human granulocytic ehrlichiosis in the mid-1990s has led to much

activity defining its geographical occurrence by serological surveys or detection in ticks by molecular methods. These studies have determined that the organism is present where the host ticks are present in Europe, Iran, North America and probably Asia.[6]

However, the disease tick-borne fever, as apposed to infection, occurs primarily in certain areas of the United Kingdom, Ireland, Norway, Finland, France, Germany, Spain, and Switzerland.[7,8] Because ticks favor particular optimal environmental conditions, the geographic distribution of the ticks is usually restricted to a specific area (small or large) and tick-borne fever only occurs in these areas. Within these areas infection can be intense and in the endemic coastal area of Norway close to 100% of sheep grazing *Ixodes* infested pastures are infected.[9] Tick-born fever has a **seasonal occurrence** in association with the feeding activity of the vector tick. Infection can be endemic in affected areas.

Sheep, cattle, goats, deer and reindeer may be infected. The disease has long been known as a disease of sheep but in recent years is being recognized as a common infection in cattle in at-risk areas.[7] The incidence rate of infection is high but clinical disease may be mild and not easily observed in many areas where this disease occurs, as these area are commonly wild with little human habitation and little frequent observation of at-risk livestock. Infection, as determined by seropositivity, can occur in sheep that have had no clinical evidence of disease because of the existence of variants with low pathogenicity.[2]

24.2.3.2

Source of infection and transmission

In Europe, *E. phagocytophila* is transmitted by the three host tick *Ixodes ricinus* which requires a single blood meal at each stage of development. The tick feeds for approximately 3 weeks every year and completes its life cycle in 3 years. The larval and nymphal stages will feed on any vertebrate but the adult female will engorge and mate only on larger mammals.

A. phagoctyophila infect and multiply in the organs of ticks, in particular the salivary glands which enables the transmission to vertebrate hosts during feeding. The tick becomes infected by feeding on an infected host and there is **trans-stadial** but not transovarial passage of the organism. It is estimated that the majority of ticks are infected with the organism in enzootic areas[10] and one study of ticks from a field site found 44% of nymphs and 32% of adults infected but no infected larval stages.[11] There is a close relation tick density and the proportion of sheep and ticks infected with *A. phagoctophila* but it is non-linear and complex.[12,13]

In the USA, *Ixodes scapularis* has been implicated in transmission of the organism in eastern USA and *Ixodes pacificus* on the west coast,[14] as have *Ixodes persulcatus* and *Haemaphysalis longicornis* in Asia[15] but clinical disease in ruminants is not a feature in these locations.

Congenital infection of a calf has occurred following experimental infection of the dam in late pregnancy[16] and the organism is also present in leukocytes in **milk** during the acute phase of the disease,[17] but the significance of this in the epidemiology of the disease is not known.

A few as one *A. phagocytophila*-infected cell may be enough to transmit infection and use of a single needle between sheep in a group could possibly transmit infection.[18]

It has been suggested that the presence of ticks in migratory birds could spread infection of this agent to other geographic regions.[19]

24.2.3.3

Experimental reproduction

The disease can be readily reproduced experimentally. The severity of the clinical response of sheep following experimental infection is not dose dependant and there is no dose effect on the degree of parasitemia or neutropenia.[18]

24.2.3.4

Host risk factors

Calves and lambs are much more susceptible than adults although clinical disease may be less severe in very young lambs[4,20] possibly due to mitigating effects of colostral antibody. Hyperimmunization of the pregnant ewe will produce high levels of colostral antibody that will protect the lamb against experimental challenge. However, in the field colostral immunity does not protect against infection and lambs born of ewes raised in endemic areas become infected. Natural infection is followed by a state of low-grade **premunity** due to the presence of the organism in the blood which provides partial resistance to subsequent infections, the disease manifesting itself in a less severe form. Once infected, animals probably remain carriers for life and act as reservoirs of infection for new generations of ticks.

The case fatality is very low and most reported mortality is in association with **intercurrent disease**. A significant indirect effect of tick-borne fever is that it increases

the susceptibility of lambs to **staphylococcal pyemia, staphylococcal pneumonia**, septicemic and pneumonic **pateurellosis**,[20] louping-ill and possibly other diseases. The mortality rate is negligible in cattle but may be higher in sheep.

24.2.3.5 Pathogen risk factors

The activity of the tick is seasonal and consequently tick-borne fever has a seasonal occurrence. The tick is active at temperatures between 7–18°C and most ticks feed in the **spring**, with peak activity dependent upon the latitude and elevation of the pasture but generally occurring in April and May. In some areas there is a second period of activity of a separate population of *I. ricinus* in the **autumn** during August and September. Clinical signs in cattle occur predominantly in spring, one to two weeks after they start to graze.

24.2.3.6 Zoonotic implications

Human granulocytic ehrlichiosis is associated with *A. phagocytophila* and was first described in the USA in 1994 and in Europe in Slovenia in 1997. It presents most commonly as an undifferentiated, febrile, potentially severe illness occurring in summer or spring associated occupational or recreational activities that allow exposure to infected ticks. There is no recognized direct zoonotic risk from exposure to infected animals but there is evidence that sheep may be one of the maintenance hosts for the organism.[2,6,9]

The organism is also present in leukocytes in **milk** during the acute phase of the disease,[17] but the risk to humans consuming this is not known.

24.2.4 PATHOGENESIS

A. phagocytophilum infect and replicate within **neutrophils** where they live in cytoplasmic vacuoles to form clusters called morulae. They are able to evade activation of the cytotoxic arsenal of the neutrophil but they do perturb neutrophil function.[21] Tissue pathology is not associated with direct *A. phagocytophilum*-mediated injury but results from immunopathologic mechanisms associated with cytokine and chemokin production.

Fever develops in association with parasitemia and is the prominent clinical abnormality in the experimental disease. It persists for approximately 8 days, may exceed 41°C, and is accompanied by depression. While this syndrome is of limited importance in the experimental setting, the occurrence of fever, dullness, and depression of the sucking drive

can be a significant influence on the viability of lambs in the cold, wet, rough-grazing areas where this disease commonly occurs and may contribute to **lamb mortality**.

Tick-borne fever produces profound effects on **immunological defense** systems. There is a significant lymphocytopenia that develops 6 days after infection and which affects all T- and B-lymphocyte subsets.[22] There is also a prolonged neutropenia lasting for 2–3 weeks combined with a thrombocytopenia. Up to 70% of the neutrophils are parasitized from the onset of the parasitemia and have **impaired function**.[10] The **antibody response** of infected sheep to immunogens such as tetanus toxoid is also impaired.[23]

1460 1461

Field observations and experimental challenge has shown that infected lambs are more susceptible to disease and mortality from **intercurrent infections.** The ability of an infection with *A. phagoctophila* to predispose to secondary disease varies with the strain of the organism[2] which may explain why secondary complications are not observed in all flock infections with tick-borne fever. There is a clear relationship between infection with *E. phagocytophila* and susceptibility to infection with *Staphylococcus aureus* and the resultant disease, **tick pyemia**. This is established both by epidemiological and experimental studies.[24]

Concurrent infection of sheep with the agent of tick-borne fever potentiates the pathogenicity of **louping-ill** virus, in experimental infections, to result in more severe disease and a higher mortality. Both diseases are transmitted by *I. ricinus*. However, in areas where both diseases are endemic, colostral immunity will delay infection of lambs with the louping-ill virus until the second year of exposure to the vector tick while allowing infection with tick-borne fever. Simultaneous primary infection with both agents may be uncommon in nature.

Infection also facilitates invasion and systemic mycotic infection with *Rhizomucor pusillus* resulting in diarrhea and dysentery and a high mortality rate.[25] Concurrent experimental infection of sheep with *E. phagocytophila* and *Chlamydia psittaci* results in **chlamydial pneumonia**[26] and simultaneous infection with parainfluenza-3 (PI-3) virus potentiates the pathogenic effect of PI-3 virus.[27] The immunosuppressive effect of tick-borne fever is believed to have resulted in the exacerbation of latent *Brucella abortus* in a naturally occurring abortion outbreak in cattle.[28] Concurrent infection of tick-borne fever and *Listeria monocytogenes* or *Pasteurella haemolytica* promotes the respective **septicemic disease** in lambs.

24.2.5 CLINICAL FINDINGS

Disease is generally benign but infection can produce abortion and can cause significant loss of weight in lambs and calves.

24.2.5.1 Cattle

In cattle there is an incubation period of 5–9 days followed by a rise in temperature to about 40.5°C (105°F) which persists for 2–12 days and for a longer period in late pregnant cows than in lactating cows.[29] The temperature falls gradually and is followed by a secondary febrile period and, in some cases, yet further episodes of **pyrexia**. During each febrile period there is a marked fall in milk yield, lethargy and polypnea and in experimentally produced cases, a mild cough although feed intake is not reduced. The fall in **milk production** can be severe and may be the first indication of infection.[30] Pregnant cattle, in the last two months of pregnancy, and placed on tick-infected pastures for the first time, commonly **abort** and occasionally animals die suddenly. The abortions occur shortly after the systemic disease. Some calves are born alive but they are weak and die.

24.2.5.2 Sheep

In sheep the syndrome is similar to that observed in cattle except that respiratory distress is not observed. However, there can be marked differences in clinical manifestation, neutropenia, antibody response, with different variants of *A. phagocytophilum*.[2]

The reaction in young lambs is quite mild and manifested only by a fever which fluctuates between 40–42°C for up to 10 days. Ewes exposed to the disease for the first time commonly experience outbreaks of abortion and affected rams are temporarily infertile.

Abortion is a major manifestation in northern Spain[8] whereas in the Scandinavian countries the main consequence of infection is immunosuppression leading to secondary infections with *Staph. aureus* (tick pyemia) and *Pasteurella hemolytica*.[31]

24.2.5.3 Goats

Tick-borne fever in goats is characterized by high fever, dullness and tachycardia.[32] See page 1464 for a description of the disease in horses.

24.2.6

CLINICAL PATHOLOGY

At the commencement of the fever there is a severe but transient **thrombocytopenia** and this is followed by more prolonged **neutropenia and lymphocytopenia**. The anaplasmae are demonstrable in the neutrophils and monocytes during each febrile period and for a few days afterwards in cattle and for several weeks in sheep; they can be detected as **intracytoplasmic inclusion bodies** in Giemsa stained blood smears, or by PCR.[17,33,34]

Serological diagnosis is possible using counter-immunoelectrophoresis which detects IgM antibody[35] or indirect immunofluorescence using cytospin preparations of blood granulocytes, which detects IgG.[7,36] Antibody is at a high level at the second week after experimental infection with both tests and is detectable for 6–8 weeks with counter-immunoelectrophoresis and for at least 18 weeks with the indirect fluorescent antibody test.[36] ELISA is also available for serological diagnosis.[9]

Transmission of the disease for diagnosis may be effected by the intravenous injection of blood taken at the height of the fever.

24.2.7

NECROPSY FINDINGS

There are no gross changes other than **splenomegaly** in sheep, and histologically the only characteristic lesion is a depletion of lymphocytes from lymphoid tissue.

Multifocal leucomalacia spongy change of white matter and swelling of oligodendrocytes is found in the brain of aborted lambs probably the result of fetal anoxia.[37]

24.2.7.1

DIFFERENTIAL DIAGNOSIS

- The geographical restriction of the disease and its relation to tick infestation are diagnostic features but the clinical signs are quite non-specific.
- The disease in cattle has some similarity to bovine petechial fever (Ondiri disease), associated with *E. ondiri*, which occurs only in Kenya.

24.2.8

TREATMENT

The best results are with **tetracyclines** or sulfadimidine although cattle may recover without therapy.[29] In sheep, a single dose of long acting tetracyclines (20 mg/kg IM) or a 5-day

course with oxytetracycline (10 mg/kg IV daily) given during the acute phase of the disease is effective in treatment but infection is not eliminated in a significant proportion of sheep.[38] In goats good results are provided by single doses of oxytetracycline (10 mg/kg BW intravenously) or a potentiated sulfonamide containing trimethoprim and sulfadimidine, and sulfamethylphenazole (20, 50, and 50 mg/kg BW respectively); ampicillin is ineffective. The anaplasmae persist in treated animals which may subsequently suffer a relapse.

24.2.9

CONTROL

Control of tick-borne fever depends upon control of the tick population. The annual dipping of ewes with organophosphates or synthetic pyrethroid acaricides will help reduce tick numbers and the double **dipping of lambs** during the tick season will help reduce disease in the lambs but can be difficult to achieve in the terrain and with the management practices of affected areas.[10] Disease is reduced if the flock can be kept off the tick-infested pastures until the lambs are 6 weeks old and if the flock is dipped prior to introduction to the pasture. In some areas it may be possible to reduce tick numbers by pasture management systems that disturb the pasture microclimate required by the tick.

1461

The disease can be more severe when adult animals are exposed to infection for the first time 1462 and **naive late pregnant cattle** should not be introduced to tick-infested pastures during the tick rise periods. A single administration of 20 mg/kg of long-acting tetracycline is reported to provide protection against experimental challenge for periods up to 3 weeks.[10] The prophylactic administration of **long-acting tetracycline** to lambs[10] and to calves[39] during the season of tick activity is reported to reduce mortality and improve growth rates over untreated controls.

24.3 HEARTWATER OR COWDRIOSIS

24.3.1 Synopsis

24.3.1.1 Etiology

Ehrlichia (*Cowdria*) *ruminantium*, a rickettsial organism

24.3.1.2 Vectors

Amblyomma variegatum and *A. habraeum*

24.3.1.3 Epidemiology

Endemic disease of cattle, sheep, goats and wild ruminants in Africa and the Caribbean; high mortality in exotic animals

24.3.1.4 Pathogenesis

Tick inoculation → local lymph node → blood → endothelial cells → vascular permeability → clinical signs and lesions.

24.3.1.5 Clinical signs

High fever, nervous signs, diarrhea and death if acute; may be mild and inapparent

24.3.1.6 Clinical pathology

Non-specific

24.3.1.7 Diagnostic confirmation

Rickettsial colonies in capillary endothelium (brain preparations)

24.3.1.8 Lesions

Ascites, hydrothorax, hydropericardium and severe pulmonary edema

24.3.1.9 Differential diagnosis list

Anthrax, rabies, cerebral babesiosis, cerebral theileriosis, meningitis or encephalitis

24.3.1.10 Treatment

Short- and long-acting tetracyclines

24.3.1.11 Control

Vaccination based on infection and treatment methods, tick control and chemoprophylaxis

24.3.2 ETIOLOGY

Ehrlichia (*Cowdria*) *ruminantium* is a Gram-negative, intracellular rickettsial organism in the tribe Ehrlichiae. It occurs in colonies or morulae with a predilection for the vascular endothelium and stains blue with Giemsa stain. The organism is coccoid, 0.2–0.5 microns in diameter. It can now be cultivated in vitro[1] and it can also grow in mice. Cyclical development is believed to take place in intestinal and salivary epithelia of ticks. Although strain differences exist, all isolates possess a major antigenic protein 1 (MAP1) that is used for diagnosis. However, the antigen cross-reacts with other *Ehrlichia* spp., including *Ehrlichia equi*, the cause of equine granulocytic ehrlichiosis.

24.3.3 EPIDEMIOLOGY

24.3.3.1 Occurrence

Heartwater is limited in its occurrence to sub-Saharan Africa, Madagascar and three Caribbean islands of Guadeloupe, Marie-Galante, and Antigua. It is one of the main causes of death in imported breeds of cattle, sheep and goats in endemic areas. Heartwater has been diagnosed recently in the island of Mayotte in the Indian Ocean.[2]

24.3.3.2 Measures of disease occurrence

In endemic areas, morbidity and mortality rates are low, but the percentage of sera positive titers for heartwater could be as high as 100% in adults,[3] depending on the abundance of tick vectors. Case mortality can be as high as 100% in peracute cases in sheep and goats and as low as 0–10% in cattle. The disease is less severe in indigenous breeds and related game animals reared in enzootic areas, some of which may become symptomless carriers. The N'Dama breed in West Africa is said to be well adapted to heartwater, partly because it can resist tick burdens under traditional farming system.[4]

24.3.3.3 Method of transmission

Heartwater is transmitted by many ticks of the *Amblyomma* genus, especially *A. variegatum* (the tropical bont tick) and *A. habraeum*, and their geographic distribution is spreading. A single infected tick can transmit the disease to cattle. In the Caribbean, cattle egrets are suspected to spread *A. variegatum* between islands. Consequently, heartwater is considered a threat to the American mainland where potential vectors are present but do not harbor the disease or where the vector may be introduced and become established. Infection in ticks is transmitted trans-stadially and possibly transovarially. Vertical transmission to calves in colostral milk has also been reported.[5] Several wild ruminants can be infected and become subclinical carriers and reservoirs. Ticks feeding on them can transmit the disease to domestic ruminants.[6] The organism does not infect humans.

24.3.3.4 Risk factors and immune mechanisms

Animals at greatest risk are exotics imported into endemic areas and at times when the vector population is high, usually during the rains. Angora goats are also highly susceptible

and therefore difficult to immunize by the current method of infection and treatment. Cattle and sheep recovering from the disease are immune for 6 months to 4 years but may be carriers for 8 months or longer. An age-dependent resistance has long been recognized and young animals were believed to have innate resistance. This was later shown to be due to low-grade infection of the young in colostral cells.[7]

24.3.4 ECONOMIC IMPORTANCE

Heartwater is the most important rickettsial infection of ruminants in Africa and the second most important tick-borne disease after East Coast fever. In southern Africa, it is regarded as the most important disease of ruminants. In general, heartwater is a more serious problem where *A. habraeum* is the vector.[8] In countries or regions where there is endemic stability, losses from heartwater are minimal until new animals are introduced. On the other hand, since most losses are in exotic animals, heartwater is a major constraint to livestock improvement in sub-Saharan Africa. Furthermore, it has the potential to spread from the Caribbean to the American mainland.

1462
1463

24.3.4.1 Biosecurity concerns

Heatwater requires the vector tick to get established in any community. Therefore, there is concern about possible illegal importation of infected animals or ticks to southern United States where potential vectors exist.

24.3.5 PATHOGENESIS

The rickettsial organisms are introduced into the host in the saliva of an infected tick. They multiply in reticulo-endothelial cells of the local lymph node, rupture the cells and are released into the circulation from where they invade endothelial cells of blood vessels in all organs. Organisms can be found in phagosomes of circulating neutrophils,[9,10] but are more abundant in endothelial cells. They cause increased vascular permeability, leading to edema especially in the lungs, body cavities and the brain, by mechanisms that are not understood, since infected endothelial cells show minimal cytopathic effects. In goats, renal ischemia and nephrosis have been described and irreversible kidney damage may be the cause of death in such cases.[11]

24.3.6

CLINICAL FINDINGS

The incubation period is 1–3 weeks after transmission in tick saliva. Depending on the susceptibility of individual animals and the virulence of the infecting organism, the resulting disease may be peracute, acute, subacute or mild and inapparent. Peracute cases show only high fever, prostration and death with terminal convulsions in 1–2 days. Acute cases are more common and have a course of about 6 days. A sudden febrile reaction is followed by inappetence, listlessness and rapid breathing followed by the classical nervous syndrome which is characteristic of heartwater. It comprises ataxia, chewing movements, twitching of the eyelids, circling, aggression, apparent blindness, recumbency, convulsions and death. Profuse, fetid diarrhea is frequent. Subacute cases are less severe but may terminate in death in 2 weeks or the animal may gradually recover. The mild form is often subclinical and is seen mainly in indigenous animals and wild ruminants with high natural or induced resistance. The case mortality rate in peracute cases is 100%, in acute cases 50–90% and in calves below 4 weeks of age it is 5–10%; most animals recover in mild cases.

24.3.7

CLINICAL PATHOLOGY

Hematological changes in heartwater are not specific but there may be thrombocytopenia, neutropenia, eosinopenia and lymphocytosis. Confirmatory diagnosis is based on identifying the rickettsia in capillary endothelial cells using a Giemsa-stained squash preparation of brain tissue at postmortem. The rickettsiae occur as blue to reddish-purple colonies or morulae of five to several hundred coccoid organisms (0.2–0.5 microns in diameter) in the cytoplasm of the cells. An immunohistochemical staining technique has also been described.[12] Injection of blood into sheep may also be used as a diagnostic procedure. The available serological test is an indirect fluorescent antibody test used for surveys but the close antigenic relationship with other *Ehrlichia* spp. often leads to false positives. An ELISA based on recombinant MAP1 protein of *C. ruminantium* was reported to be more sensitive.[13] In general, clinical detection of heartwater is not always easy because all serological assays so far available have poor sensitivity or specificity.[14] A polymerase chain reaction assay has therefore been suggested as the method of choice for detection of *E. ruminantium* infection.

24.3.8

NECROPSY FINDINGS

Standard lesions are ascites, hydrothorax and hydropericardium. Pulmonary edema is often severe, accompanied by copious froth in the tracheobronchial airways. There may be

subserosal hemorrhages in most cavities. Lymph nodes are swollen and wet and the spleen is markedly enlarged. In goats with nephrosis, the kidneys will be soft. Although hemorrhages have been described in the brain, it often has no remarkable gross lesions but microscopically, there is perivascular mononuclear infiltration and edema along with presence of rickettsial colonies in capillary endothelial cells. Foci of malacia may be present. Tissues for histopathology should include brain, lungs, lymph nodes, spleen and kidneys.

24.3.8.1

DIFFERENTIAL DIAGNOSIS

- In endemic areas, heartwater should be suspected in susceptible animals infected with *Amblyomma* and having a fever of unknown origin, especially when accompanied by nervous signs. The clinical and pathological findings are not specific and the diagnosis must be based on detection of rickettsial organisms.
- The peracute form should be differentiated from anthrax and the acute form from rabies, sporadic bovine encephalomyelitis, tetanus, cerebral forms of theileriosis, babesiosis, trypanosomosis, meningitis, listeric or other encephalitis, hypomagnesemia and poisoning with strychnine, lead and organophosphates. Appropriate laboratory tests are utilized to eliminate these differentials.

24.3.9

TREATMENT

Field cases of heartwater are difficult to treat successfully because available drugs are effective only in early febrile stages before neurological signs develop. In the early stages, short-acting tetracyclines at 10–20 mg/kg BW and long-acting forms at reduced doses are effective. Sulphonamides can also be used in the early stages but are less effective. Hyperimmune serum is said to be of no curative value. Supportive therapy to reduce either the pulmonary edema or the neurologic signs or to stabilize membranes in general are being investigated but with little success.

Chemoprophylaxis involves administration of tetracyclines or subcutaneous implantation of doxycycline in susceptible animals when they are introduced into an endemic area. Results are not always predictable.

24.3.10

CONTROL

Past efforts to control heartwater were based on intensive acaricide treatment in endemic areas. It involved frequent use of acaricides (plunge dipping) up to 52 times a year. This has

now been shown to be environmentally unfriendly, economically unsustainable, and would invariably lead to animals that remained always susceptible.[15] For example, it was observed in Zimbabwe that large farms applying acaricides very frequently (more than 30 times per annum) had higher morbidity and mortality than farms applying acaricides less frequently.[16] What is advocated today is integrated control based on the establishment of endemic stability by vaccination or natural challenge. Vaccination is based on infection and treatment regimen that was first developed more than 50 years ago.[17] It involves an intravenous injection of virulent organisms in cryopreserved sheep blood, followed by treatment with tetracyclines at the first indication of fever. The exposure of calves and lambs up to 3 weeks of age, without treatment, is considered optimal for the development of resistance but kids may still be susceptible. Vaccination may lead to some deaths, the immunity may wane in absence of reinfection, and animals may become carriers.[1,18] More recently, cattle were successfully immunized for up to 10 months with a killed vaccine from a lysate of *E. ruminantium* 1463

formulated in Freund's adjuvant.[19] In another study, the use of inactivated vaccines from cell-cultured *E. ruminantium* combined with an adjuvant led to a reduction in mortality from heartwater in cattle, sheep and goats exposed to field challenges in Botswana, Zambia, Zimbabwe, and South Africa.[20] Experimental studies using DNA recombinant vaccines so far have met with only limited success.[17,21] 1464

For tick control, flumenthrin 1% pour-on at 45 days interval was found to provide effective protection of Friesian/Zebu crossbred cattle against important ticks, but it must be applied correctly at the recommended dose.[22] Pure Zebu and N'Dama cattle would probably require less frequent applications. Flumenthrin pour-on is gradually replacing plunge dipping for the control of ticks and tickborne diseases in general. Other than routine surveillance, there are no special biosecurity concerns with heartwater, since transmission requires presence of the vector.

24.4 EQUINE GRANULOCYTIC ANAPLASMOSIS (EQUINE GRANULOCYTIC EHRLICHIOSIS, *ANAPLASMA PHAGOCYTOPHILA*

Anaplasma phagocytophila causes disease of horses, humans, dogs, cattle, cats, and other mammalian species, that is characterized in horses by fever, depression, limb edema, icterus and ataxia. The disease is described here with emphasis on that occurring in horses. See 'Tick-bone fever' for a description of the disease in other species.

24.4.1 ETIOLOGY

The disease in horses is associated with the same agent that causes human granulocytic ehrlichiosis (HGE).[1] The organisms *Ehrlichia equi*, *E. phagocytophila*, and the HGE agent are now classified as *Anaplasma phagocytophila*.[1] The variety of species affected and geographical distribution of the disease suggests strains of *Anaplasma phagocytophila* of varying pathogenicity and host specificity. For example, while *A. phagocytophila* is a recognized cause of tick-borne fever in cattle, sheep, and goats in Europe, the disease has not been recognized in the United States despite the widespread occurrence of this organism in North America. *A. phagocytophila* infects some domestic and wild ruminants, including deer, without inducing clinical signs.[1] The HGE agent causes tick-borne disease in horses identical to that associated with *E. equi* and horses infected with HGE are resistant to subsequent challenge with *E. equi*.[2,3] *Anaplasma phagocytophila* is an obligate intracellular bacterium that replicates in cells derived from the bone marrow (granulocytes).

Anaplasma phagocytophila also causes disease in humans, dogs, domestic ruminants, and cats.[1,4] As mentioned above, the geographic distribution of *A. phagocytophila* does not match the distribution of disease in all species, suggesting that strains of differing pathogenicity for various species occur. Indeed, strains of *A. phagocytophila* that cause disease in dogs and horses in southern Sweden differ slightly in their genetic composition from isolates derived from North America.[5] Similarly, nucleotide sequences of strains of *A. phagocytophila* from the west coast of the United States differ from those of strains originating from the east coast.[6]

24.4.2 EPIDEMIOLOGY

24.4.2.1 Distribution

The disease in horses occurs in the Americas (the United States including California, Washington, Oregon, Minnesota, Wisconsin, and the southeastern and the northeastern states, and Brazil), France, Italy, Switzerland, Sweden, Germany, and the United Kingdom.[4,7–9]

The **prevalence** of horses with serum antibodies to *E. equi* (*A. phagocytophila*) in endemic areas of California is 10%, compared with 3% in areas where the disease is uncommon.[10] On farms where the disease occurs frequently, 50% of horses have serum antibodies to *E. equi* (*A. phagocytophila*).[10] Approximately 18% of horses in areas of the upper Midwest of the United State in which *Ixodes* sp. ticks are endemic have antibodies to *E. equi* (*A. phagocytophila*) whereas 4 % of horses in areas in which the tick does not occur are seropositive.[11] A survey of 563 horses in Lazio region of Italy (near Rome), where the disease in horses occurs, revealed a seroprevalence of 0.3%.[12]

There is extensive evidence of exposure of dogs to *A. phagocytophila* and of disease consistent with granulocytic ehrlichiosis. 47% of dogs in endemic areas in California have antibodies to *E. equi* (*A. phagocytophila*) and some show clinical signs consistent with the disease.[13,14]

A total of 0.2% of 2725 serum samples from cattle in California had detectable antibodies to *A. phagocytophila*.[15] Forty-three to 96% of deer and moose, respectively, in Norway are seropositive to *E. equi* (*A. phagocytophila*), indicating the widespread extent of exposure of these species to the organism.[16]

24.4.2.2 *Anaplasma* and *Ixodes* ecology

A. phagocytophila is maintained by infection in wild cervids (such as the white tailed deer in North Eastern United States) and small mammals such as the white footed mouse or dusky-footed wood rat.[1,4] Infection of horses, dogs, and humans occurs through the bite of *A. phagocytophila*-infected ticks.[4] *E. equi* (*A. phagocytophila*) is detectable using a polymerase chain reaction test in *I. pacificus* that have fed on *E. equi* infected horses[17] and infected *I. pacificus* can cause granulocytic ehrlichiosis in previously unexposed horses.[18]

The organism is transmitted by hard ticks that are members of the *Ixodes persulcatus* complex, which includes *Ixodes pacificus*, *Ixodes scapularis*, and *Ixodes ricinus*.[1,4] Transstadial, but not transovarial, transmission occurs. The tick vectors of *A. phagocytophila* pass through four stages in their life-cycle:[4] egg, larva, nymph, and adult. Maturation from larva to nymph and from nymph to adult, and egg laying, all require the ingestion of a blood meal. As transovarial transmission of infection does not occur, larvae or uninfected nymphs become infected by feeding on an infected mammal. The engorged and infected immature tick then dismounts and matures to the next life stage away from a mammalian host. When the immature tick reaches the nymph or adult stage, it again seeks a mammalian host. Transmission of the infection from the tick to a mammal occurs through feeding of an infected nymph or adult on a susceptible host.

1464

1465

24.4.2.3

Animal risk factors

Horses that have not been exposed to *A. phagocytophila* are susceptible to infection and disease. There is a marked seasonality of the disease in California with most cases occurring in late autumn, winter, and spring.[19]

Anaplasma phagocytophila infects domestic ruminants in Europe where it causes tick-borne fever.[20] However, cattle infected with HGE agent or *A. phagocytophila* isolated from horses with the disease in the United States do not develop clinical signs of disease nor do they have detectable *A. phagocytophila* morulae in blood, although they do seroconvert.[15] This study, and the low seroprevalence of antibodies to *A. phagocytophila* in cattle in California indicate the organism rarely, if ever, causes disease in cattle in these geographic regions.

Infection in horses is followed by a solid immunity and recovered animals are resistant to the disease for at least 20 months although it is suggested that reinfection and disease can occur.[21] Serum antibodies persist for at least 300 days after infection in some horses but decrease to low levels in most horses by 200 days after infection.[21–23]

24.4.2.4

Transmission

As discussed above, transmission is through the bite of an infected tick. Transmission through use of blood contaminated veterinary equipment or by blood transfusion is

possible, the later being used to induced disease in experimental challenges. Perinatal transmission of *A. phagocytophila* is reported in humans.

24.4.2.5

Morbidity and mortality

The **case fatality rate** is low, approximately 4%, and deaths of horses with uncomplicated disease are rare.[19]

24.4.2.6

Zoonotic potential

There is no evidence that infection spreads directly from infected horses or dogs to humans. However, dogs have been suggested to be sentinel animals in that humans in areas in which dogs have a high prevalence of antibodies in serum to *A. phagocytophila* might be at increased risk of infection from bites of infected ticks.[14]

24.4.3

PATHOGENESIS

The pathogenesis of the disease is poorly understood. Following experimental infection, horses have organism detectable by PCR beginning 5 days after infection, with development of fever and depression 7–8 days after infection. Inclusions in granulocytes are detectable beginning 9 days after infection, at which time there is edema of the limbs.[24] The disease in horses is associated with rapid changeover of expressed p44 genes such that there is marked antigenic variation in the major surface protein, p44, during infection in an animal.[25] The rapid changeover of expression of p44 is attributed to development of specific antibody to the hypervariable region of p44.[25] Infection in sheep results in immune suppression secondary to granulocytic and lymphocytic leukopenia, impaired antibody production, reduced lymphocyte response to mitogens, and a decreased oxidative burst activity of neutrophils.[26] The prominent clinical sign of edema is likely related to the vasculitis that is characteristic of the disease.

24.4.4

CLINICAL SIGNS

The **incubation period** for the spontaneous disease is less than 2 weeks. Subclinical infections are believed to be common, based on the number of horses with serologic evidence of infection but no history of disease.

Clinically there is high fever of 40–42°C (104–107°F) followed by mucosal pallor, jaundice, anorexia, depression, increased respiratory movement, incoordination and reluctance to

move and, after 3–4 days, **edema** and heat of the extremities.[24] There may be petechial hemorrhages on mucosal membranes. The edema persists for 7–10 days and clinical signs resolve in 14 days. Clinical disease is more severe in horses over 3 years of age and is minor in young horses.[19] Severely affected horses can have signs consistent with neurologic disease, including ataxia, defects in conscious proprioception, and recumbency.[23]

Arrhythmias may occur during the acute phase of the disease. Chronic infection and disease is not recognized.

24.4.5 CLINICAL PATHOLOGY

Hematological examination may reveal a mild anemia and leukopenia. **Thrombocytopenia** is common in the acute stage of the disease. There are no consistent serum biochemical abnormalities.

Positive identification of the disease is made on the presence of inclusion bodies (morulae) in the cytoplasm of neutrophils and eosinophils. Careful and protracted microscopic examination of a blood smear, stained with Giemsa, may be necessary to identify the inclusions (morulae). The inclusions are apparent as pleomorphic, blue-gray color bodies, often in a spoke wheel formation, in the cytoplasm of granulocytes.[19] The number of infected cells may be quite small and examination of a buffy coat preparation may increase the sensitivity of the test.

Diagnosis is achieved through use of a polymerase chain reaction test to identify *Anaplasma phagocytophila* DNA in blood samples of infected horses and by demonstration of an increase in antibody titer detected by indirect fluorescent antibody staining.[10] However, antibody titers are low to undetectable in approximately 44% of horses with at the onset of clinical signs, and reach a maximum within one month of infection.[23,24] An ELISA that detects antibodies against the p44 surface antigen of *A. phagocytophila* is suitable for use in dogs and horses.[27]

24.4.6 NECROPSY EXAMINATION

At **necropsy** there are petechiae and edema of the legs and at histological examination there is a vasculitis. There are often inflammatory lesions in the brain, heart and kidneys.

24.4.6.1

DIFFERENTIAL DIAGNOSIS

Differential diagnoses include: equine infectious anemia, which has a much more protracted course and does not respond to treatment; purpura hemorrhagica, which is often associated with infectious upper respiratory tract disease; liver disease, viral encephalitis; equine herpesvirus 1 myeloencephalopathy, ***rabies***, botulism, and equine viral arteritis.

24.4.7

TREATMENT

The specific treatment is oxytetracycline (7 mg/kg BW IV, every 24 hours) for approximately 5–7 days. Penicillin, streptomycin and chloromycetin are not effective. The response to treatment with oxytetracycline is rapid and the fever is reduced or eliminated in 12–24 hours, and signs of the disease resolve within 5–7 days in most horses. Inclusion bodies are difficult to find 24 hours after beginning treatment. Without treatment the disease is usually self-limiting to 2–3 weeks.

24.4.8

CONTROL

There is no **vaccine**, and specific control measures cannot be recommended at this time, although minimizing access of ticks to horses would appear prudent. There is no need to isolate infected horses.

24.5 EQUINE NEORICKETTSIOSIS (EQUINE MONOCYTIC EHRLICHIOSIS, EQUINE EHRLICHIAL COLITIS, POTOMAC HORSE FEVER)

24.5.1 Synopsis

24.5.1.1 Etiology

Neorickettsia risticii, a rickettsia. Infection occurs by ingestion of aquatic insects (caddis flies) infected by the organism

24.5.1.2 Epidemiology

An infectious, but not contagious, sporadic disease of horses in North and South American and parts of Europe. Localized epidemics may occur. Disease is most common near large rivers, but can occur elsewhere

24.5.1.3

Clinical signs

Fever and diarrhea with colic and laminitis in severe cases. Abortion is a sequela of clinical disease in mares

24.5.1.4

Lesions

No gross lesions, except for laminitis. Histologic evidence of typhlitis and colitis

24.5.1.5

Diagnostic confirmation

Demonstration of *N. risticii* by PCR or cultivation, in blood or feces of sick horses. More commonly the presence of a high antibody titer in horses with appropriate clinical signs is considered diagnostic

24.5.1.6

Treatment

Oxytetracycline (6.6 mg/kg, IV every 24 hours), fluids, and supportive care. Prophylaxis for laminitis

24.5.1.7

Control

Vaccination, of questionable efficacy

24.5.2

ETIOLOGY

The causative agent is *Neorickettsia risticii*, formerly named *Ehrlichia risticii*, a small Gram-negative coccus that is closely related to the agents of human ehrlichiosis (*E. sennetsu*) and salmon poisoning of dogs (*Neorickettsia helminthoeca*).[1]

24.5.3

EPIDEMIOLOGY

The disease is infectious, but not contagious, and usually has a sporadic occurrence. Localized epidemics may occur.

24.5.3.1

Occurrence

Equine neorickettsiosis is recorded in the United States, Canada, Europe, Uruguay and southern Brazil.[2] While it might have wider occurrence, evidence of infection based on the

commonly used indirect fluorescent antibody test should be interpreted with caution because of the high rate of false positive results.[3] The highest prevalence of disease is near large rivers, apparently related to the infection of horses by ingestion of infected aquatic insects, although the disease can occur elsewhere.[4]

Clinical disease is sporadic and seasonal with the predominance of cases occurring during the summer and the autumn periods in areas with cool to cold winters.[5] In warmer areas, such as Florida and Texas, cases occur year round. The prevalence of horses in the mid-west and east coast of the United States with antibodies to *N. risticii* varies with geographical region, but can be as high as 86% of horses tested, although the overall rate appears to be closer to 25%.[4] The prevalence of horses with serological evidence of exposure is much less in California.[3] There is a marked seasonal variation in the prevalence of seropositive horses, with the highest prevalence being in the summer months (July and August) and the lowest prevalence being in the winter.[6]

24.5.3.2

Animal risk factors

Clinical disease is believed to be uncommon in horses under 1 year of age, although peracute disease can occur in foals,[7] and there is no age difference in prevalence of disease in adult horses.[5] Similarly, there is no evidence that breed and sex influence susceptibility to disease.[5] The risk for disease is greater in horses housed on premises with a history of previous infection or those that have other livestock.[5]

The clinical attack rate varies considerably, but estimates range between 0.44 and 19 cases per year per 1000 horses at risk.[5,8] During epidemics, the clinical attack rate may be as high as 20–50% of horses on affected farms.[9] **Case fatality** rates as high as 30% were initially reported for horses with clinical disease but with the subsequent improved recognition and early treatment the case fatality rate is currently closer to 7%.

The risk of horses being seropositive in some areas is related to breed (Thoroughbreds are three times more likely to be seropositive than are non-Thoroughbreds and non-Standardbreds), sex (females are 2.7 times more likely to be exposed than are stallions and geldings), and age (increasing risk up to 12 years of age).[10] Horses that have had clinical signs compatible with neorickettsiosis are more likely to be seropositive than are horses with no such history.[11]

24.5.3.3

Transmission

The disease is infectious but not contagious.[5] Horses develop infection and disease after ingestion of aquatic insects including caddis flies (*Dicosmoecus gilvipes*).[12,13] The disease can be transmitted experimentally to horses by parenteral administration of *N. risticii* or blood from infected horses.[14] Studies of a tick (*Dermacentor variabilis*), black flies (*Simulium* spp.), fleas, flies (*Tabanus* spp., *Hybomitra* spp., *Stomoxys* spp., *Haematobia* spp.), and mosquitoes, have failed to demonstrate transmission of infection.

The complete life cycle of *Neorickettsia risticii* has not been elucidated, but it is known that the organism infects trematodes stages (cercariae and xiphidiocercariae) found in freshwater snails (*Juga* sp. in California and *Elimia sp*. in Ohio).[15,16] *Neorickettsia risticii* infects metacercariae found in adults and juveniles of aquatic insects including caddis flies (Trichoptera), mayflies (Ephemeroptera), damselflies (Odonata, Zygoptera), dragonflies (Odonata, Anisoptera), and stoneflies (Plecoptera).[17] *N. risticii* DNA has been detected in trematodes (Lecithodendriidae) infecting bats and swallows.[18,19] *N. risticii* DNA is present in eggs of the trematodes (*Acanthatrium oregonense*) found in bats demonstrating vertical (adult to egg) transmission of infection in trematodes.[19] Furthermore, *N. risticii* DNA was detected in the blood, liver or spleen of bats infected with the trematode, suggesting that *N. risticii* can also be transmitted horizontally from trematode to bat.[19] These results indicate that the trematode *A. oregonense* is a natural reservoir and probably a vector of *N. risticii*. This information suggests that insectivorous bats and birds are the definitive hosts of trematodes that maintain the natural reservoir of *N. risticii*.[18] Briefly, it appears that horses are accidentally infected by *N. risticii* that normally cycles between trematode life stages in bats, fresh water snails, and aquatic insects.

Infected horses develop a sterile immunity and so are unlikely to be a source of subsequent infection.

24.5.4

PATHOGENESIS

Infection is followed by monocyte-associated bacteremia and the organism is present in monocytes, macrophages and the glandular epithelial cells of the intestinal tract. The number of *N. risticii* in blood is greatest before the development of clinical signs, which in experimentally infected horses and ponies occurs approximately 19 days after infection by ingestion of infected aquatic insects.[13] The prominent clinical sign of diarrhea is due to

colitis and typhlitis and is associated with an neorickettsia-induced disruption of sodium and chloride absorption by the large colon.[20] Fluid and electrolyte losses associated with the diarrhea cause dehydration, hyponatremia and acidosis. Transplacental infection with *N. risticii* occurs and causes abortion.[21]

1466
1467

24.5.5 CLINICAL FINDINGS

The classic manifestation of *N. risticii* infection in horses is fever, depression, anorexia, diarrhea, colic, and laminitis. However, infection can result in a variety of clinical abnormalities ranging from inapparent infection, through transient fever and depression, to the severe signs described above. Equine neorickettsiosis should be considered in any horse living in an endemic area that demonstrates fever and depression.

In naturally occurring cases of severe clinical disease there is typically an acute onset with depression, anorexia, tachycardia, congested mucous membranes and fever up to 107°F. There are decreased intestinal sounds on abdominal auscultation in the early stages of the syndrome and subsequently tinkling sounds prior to the onset of diarrhea which usually occurs 24–72 hours later. The severity of the diarrhea varies but it is usually profuse and projectile. It persists for up to 10 days and there may be sufficient fluid loss to result in severe and rapid dehydration and hypovolemic shock. Colic is a presenting sign in some horses and may be mild or present as an acute abdomen. Laminitis occurs in up to 40% of horses and is usually apparent within 3 days of initial signs of disease. There can also be subcutaneous edema in the ventral abdomen and limbs. Less severe clinical manifestations of infection include the occurrence of fever and anorexia without other signs, or the occurrence of mild colic or subcutaneous edema.

Abortion occurs as a result of *N. risticii* infection and, in experimental infections, occurs 65–111 days after infection of the dam. The dams that aborted all became clinically ill after infection, but clinical signs of disease had resolved at the time they aborted.[21] Abortion was presaged by ventral edema and enlargement of the udder, and placenta was retained in some cases.[21]

24.5.6 CLINICAL PATHOLOGY

Hematological examination usually reveals leukopenia (<5000 leukocytes per μl) with neutropenia and a marked left shift, mild thrombocytopenia, and hemoconcentration (hematocrit 50–60%, 0.5–0.6 L/L). **Serum biochemical analysis** often reveals

hyponatremia, hyperkalemia, hypochloremia, metabolic acidosis and azotemia. **Peritoneal fluid** is usually normal.

Diagnostic confirmation is achieved by demonstration of *N. risticii* in blood or feces, or serological evidence of infection, in horses with clinical signs compatible with the disease. Routine diagnosis is based on demonstration of a high serum antibody titer on the indirect immunofluorescent antibody (IFA) test.[11] Most horses with disease due to *N. risticii* have titers ≤1:80 at the onset of clinical signs while horses with titers ≥1:40 probably do not have the disease.[11] The presence of a high titer at the time of onset of clinical signs is a result of the 8–12 day incubation period during which there is a high level neorickettsemia and the production of a strong IgM antibody response.[22] The IgM antibody response wanes rapidly and may be undetectable by 60 days after infection, although a prominent IgG response occurs.[22] Therefore, by the time clinical signs are apparent the horse has a high titer that might decline, making the use of acute and convalescent (2 weeks after clinical signs resolve) serum titers potentially misleading. A rising titer in samples collected several days apart soon after the onset of disease is indicative of the disease, but a declining titer does not rule it out. The IFA test performed in some laboratories has a high rate of false-positive reactions.[3]

Detection of the organism in white blood cells by microscopic examination of stained blood smears is usually not possible because of the low level of infection of blood monocytes. The organism can be cultivated but this is time consuming and expensive. However, a test that detects the presence of *N. risticii* nucleic acid by the polymerase chain reaction has a sensitivity similar to that of blood culture in experimental infection.[23] Similarly, *N. risticii* can be detected by a polymerase chain reaction test in feces of horses with disease.[24]

24.5.7 NECROPSY FINDINGS

The gross changes in horses dying of EME usually include subcutaneous edema of the ventral body wall and a very fluid consistency to the contents of the large bowel. Congestion, hemorrhage and mucosal erosions can occur throughout the alimentary tract but are concentrated in the cecum and colon. The mesenteric lymph nodes are often swollen and edematous. There may be lesions of laminitis. Histologic examination confirms the alimentary mucosal erosion and ulceration, which is accompanied by an infiltrate of a mixed population of leukocytes within the lamina propria and submucosa. The causative organisms can be demonstrated in tissue sections using Steiner's silver stain. Detection using electron microscopic or PCR techniques are other options.

Fetuses that are aborted as a result of *N. risticii* infection of the dam have histologic evidence of enterocolitis, periportal hepatitis and lymphoid hyperplasia with necrosis of mesenteric lymph nodes.[21]

24.5.7.1 ## Samples for postmortem confirmation of diagnosis

The parasite can be demonstrated in cecum, colon, and mesenteric lymph node by a polymerase reaction test or electron microscopy. Formalin-fixed tissue for light microscopy should include cecum, colon, liver and mesenteric lymph node.

24.5.7.1.1 ## DIFFERENTIAL DIAGNOSIS

The main differentials are as follows (Table 5.14):

- Diarrhea due to: salmonellosis, *Clostridium difficile* colitis, massive emergence of hypobiotic cyathostomes, colitis X, and antibiotic-induced colitis
- Abortion due to: EHV-1, leptospirosis, congenital anomalies, and *Salmonella abortusequi*.

24.5.8 ## TREATMENT

The specific treatment of equine neorickettsiosis is oxytetracycline (6.6 mg/kg BW IV every 24 hours for 5 days) and horses treated early in the disease respond well. Given the effectiveness of oxytetracycline in the treatment of the disease and the lack of clear evidence that oxytetracycline at the recommended dose induces or exacerbates diarrhea, this drug should be administered to all horses that live in an endemic area and that develop signs consistent with equine neorickettsiosis. Treatment does not interfere with the development of immunity.[25] Other antibiotics that have been used include combinations of a sulfonamide and trimethoprim or rifampin and erythromycin. Doxycycline has been used, but intravenous administration is associated with cardiovascular abnormalities and sudden death.[26]

Treatment of horses with acute diarrhea is discussed under Acute diarrheas of horses. Prophylaxis for laminitis may be useful.

24.5.9

CONTROL

Control centers on vaccination although it is of unproved efficacy in field situations. The apparent lack of efficacy of vaccination in the United States might be due to the inclusion of only one strain of *N. risticii* in the vaccine. There is evidence of the presence of a number of strains of the organism and the vaccine might not confer immunity to all these strains.

Infection is followed by the development of a neutralizing antibody response that is associated with clearance of *N. risticii* and the presence of a sterile immunity which persists for at least 20 months.[27,28] An inactivated whole cell adjuvanted vaccine is available and vaccinated animals have resistance to experimental challenge.[25] However, protection from vaccination is not complete and wanes within 6 months. In an area with a low attack rate of the disease (0.44–1.7 horses/1000 per year) the risk of neorickettsiosi in horses vaccinated once per year is almost identical (odds ratio = 0.93) to that of unvaccinated horses, and there is no difference in the severity of the disease in vaccinated and unvaccinated horses.[29] Furthermore, it is more economical *not* to vaccinated horses in areas with a low attack rate.[30] In areas with a high attack rate it may be appropriate to provide an initial vaccination of two doses 3 weeks apart with revaccination at 4-month intervals during the disease season.[25]

24.6 ‘Q’ FEVER

24.6.1 Synopsis

24.6.1.1 Etiology

Coxiella burnetii

24.6.1.2 Epidemiology

High seroprevalence in ruminants. Latent infection with recrudescence and excretion at parturition. Infection by direct contact and inhalation. Important zoonotic disease

24.6.1.3 Clinical findings

Infection in ruminants common but clinical disease is rare and presents mainly as abortion in sheep

24.6.1.4 Necropsy findings

Placentitis. Organisms demonstrable in trophoblast cells by fluorescent antibody

24.6.1.5 Diagnostic confirmation

Fluorescent antibody staining and PCR. Serology for herd infection status

24.6.1.6 Control

Isolation of aborting ruminants. Vaccination possible

24.6.2 ETIOLOGY

Q fever is a zoonosis associated with *Coxiella burnetii* which is an obligate intracellular parasite classified within the family Rickettsiaceae and which can be divided into six genomic groups on the basis of restriction fragment length polymorphism. Unlike other *Rickettsiae* members *C. burnetii* it is quite resistant to environmental influences and is not dependant upon arthropod vectors for transmission. *C. burnetii* displays two antigenic phases, phase 1 and phase 11. Phase 1 organisms are more infectious.

24.6.3 EPIDEMIOLOGY

24.6.3.1 Occurrence

The organism has **worldwide distribution** although a large serological survey argues that it is not present in New Zealand.[1]

C. burnetii cycles in a wide variety of wildlife species and their ectoparasites. The infection also cycles in domestic animals; cattle, sheep and goats are the main livestock reservoirs of infection for humans.[2,3] Rates of infection in farm animals vary considerably between locations, between countries and with time as there appears to be cycles of infection within regions.

In cattle, prevalence figures range from 6–82% of cattle and 23–96% of herds seropositive depending upon location and country.[4–7] Seropositivity rates in sheep and goats are similar but also vary according to year and region.[8–11] There is little information on management or other factors that might influence this variation in prevalence but one study found a significantly higher prevalence in housed cattle compared to cattle at pasture kept at pasture.[7]

24.6.3.2

Source of infection and transmission

Infection and transmission is by direct contact and by inhalation. Infection of non-pregnant animals is clinically silent and is followed by latent infection until pregnancy when there is recrudescence with infection in the intestine, uterus, placenta and udder and excretion from these sites at parturition. The organism is present in high concentration in the **placenta** and **fetal fluids,** and subsequent vaginal fluids, is also excreted in **urine** and is present in the **feces** of sheep from 11–18 days post partum.[2,12] Infection can result in abortion, stillbirths or poorly viable lambs but commonly the neonates of infected, excreting, ewes are born clinically normal. Abortion usually does not occur at successive pregnancies but there can be recrudescence of infection and excretion at these pregnancies, especially the one immediately following.[13,14]

Goats also excrete the organism in vaginal discharges for up to 2 weeks, and it is present in goat milk for up to 52 days after kidding and also in feces.[15] Maximum shedding in **cattle** also occurs at parturition and for the following two weeks but cattle excrete the organism in the milk for at least several months and up to 2 years[2] and infection is common in bulk tank milk.

As with sheep, infection in goats can be accompanied by abortion but abortion in cattle is rare although it is recorded.[9,16]

There is a significant contamination of the environment of infected animals at the time of parturition and this is probably a major period for transmission of the disease within herds and flocks.[17]

The organism is present in the semen of seropositive bulls and venereal transmission is suspected.[18]

24.6.3.3

Pathogen risk factors

C. burnetii is very **resistant** to physical and chemical influences and can survive in the environment and soil for several months. It can resist common chemical disinfectants but is susceptible to sodium hypochlorite, 1:100 lysol solution and formalin fumigation provided a high humidity is maintained.[19]

There is strain variation in the organism and differences in plasmid sequence types have been correlated with differences in the type of disease occurring in humans. The organism is highly infectious and it is estimated that the infective dose for humans approximates one organism.[20]

24.6.3.4

Zoonotic implications

In humans infection is primarily by **inhalation**. Sources of infection include such diverse materials as soil, air-borne dust, wool, bedding and other materials contaminated by urine, feces or birth products of animals. The potential for human infection from these sources is substantial; for example, ovine manure used as a garden fertilizer has been incriminated as a source.[21]

Sheep have traditionally been incriminated as the major reservoir of infection for humans but the trend for urban populations to locate in close proximity to large dairy herds suggests that cattle could become an increasingly significant reservoir.

The organism is present in the **milk** of infected cattle, sheep and goats. A significant proportion of seropositive cattle excrete the organism in milk and periods and duration of excretion are variable but may persist at least 2 years.[2] *C. burnetii* is destroyed by pasteurization but there is a risk for the farm family that consumes raw milk and a particular concern for the occurrence of the organism in raw sheep and goats' milk.

Rates of seropositivity in humans vary markedly between surveys but there is a higher rate of seropositivity in people (farm workers, veterinarians, livestock dealers, dairy plant and slaughter house workers, shearers, etc.) that are associated with domestic animals and their products and with farm environments.[8,22–24] Several incidents of infection in humans have been linked to exposure to **parturient** sheep and goats.[2,8,10,25]

The infection in humans is also commonly asymptomatic but can result in disease characterized by fever, general malaise, headache, and less commonly, pneumonitis, hepatitis and meningoencephalitis. Endocarditis and hepatitis are manifestations of chronic disease. Immunocompromised persons are at greater risk for disease. There is a concern that the prevalence of infection in farm animals is increasing and spreading geographically and that there is a subsequent greater risk for infection in humans.[10,14,26]

C. burnetii is considered a potential agent for bioterrorism because of its survival in the environment, the ease with which it can transmit by aerosol and windborne means and the very low infectious dose.

24.6.4 CLINICAL FINDINGS

Infection of ruminants can occur at any age and is usually clinically inapparent. In the experimental disease in cattle, anorexia is the only consistent clinical finding. *C. burnetii* is a cause of abortion in sheep and goats. Abortion occurs during the latter part of the lambing period in the flock and in the latter period of pregnancy in individual ewes. The dam shows no signs of impending abortion. In cattle the organism is a rare cause of abortion. Correlations between herd level seroprevalence and herd fertility are equivocal.[5,6,27]

24.6.5 CLINICAL PATHOLOGY

There are a number of serological tests available including complement fixation, micro agglutination, ELISA and indirect immunofluorescence.[28]

The immunofluorescence assay is used as the sero-reference test for the serodiagnosis of Q fever. It can detect antibody to phase variants and can provide epidemiological information as phase 11 antibody is associated with recent and acute infections and phase 11 antibody with chronic infections.[14]

24.6.6 NECROPSY FINDINGS

There are seldom gross lesions in aborted fetuses, but foci of necrosis and inflammation are occasionally seen in the liver, lung, and kidney microscopically. The placenta from aborting animals is usually thickened and a purulent exudate or large, red-brown foci of necrosis are typically seen in the thickened intercotyledonary areas. Microscopically, large numbers of necrotic neutrophils are usually visible on the chorionic surface and swollen trophoblasts

filled with the organisms can also be found in well-preserved specimens. Examination of placental impression smears stained with Gimenez, Koster's, or other appropriate techniques provides a means of rapid diagnosis. However, care must be taken to avoid confusing *Coxiella*-infected trophoblasts with cells containing *Chlamydophila* organisms. Coxiellosis can be confirmed fluorescent antibody staining of fresh tissue or immunohistochemical staining of formalin-fixed samples. In most laboratories, culture is not attempted due to the zoonotic potential of this agent.

24.6.6.1 Samples for confirmation of diagnosis

- **Bacteriology** – chilled placenta (CYTO, FAT)
- **Histology** – fixed placenta, lung, liver, kidney (LM, IHC).

Note the zoonotic potential of this agent when handling carcasses and submitting specimens.

24.6.6.1.1 DIFFERENTIAL DIAGNOSIS

- The diagnosis of the disease in farm animals, other than abortion, suspected as associated with this agent is difficult and relies upon the detection of the organism
- A positive serological test in an animal or herd is indicative of infection at some time but does not indicate an association with the problem at hand
- PCR or PCR-ELISA has been used for detection of the organism in milk.[29]

24.6.7 CONTROL

Aborting animals should be isolated for 3 weeks and aborted and placental-contaminated material burnt. Ideally, manure should be composted for 6 months before application to fields. Feed areas should be raised to keep them free from contamination with feces and urine.

While Q fever has significant implications for human health, it is not significantly important enough to have generated national or regional control strategies based on control in the animal population.

Milk and milk products should be pasteurized. Veterinarians dealing with herds that provide raw milk should insure that these herds are seronegative for *C. burnetii*.

Vaccine trials with killed vaccines in animals show a good and persistent antibody response and suggest that vaccination can limit the excretion of the organism.[30] However, there is little economic incentive for a vaccination program involving livestock and livestock vaccines are not available in most countries.

Vaccination of humans has reduced infection rates in high risk groups and has been used in the appropriate circumstances in Australia.[31] As defined by recognized infections, personnel in research facilities that contain sheep are at greatest risk for infection and management guidelines for the control of 'Q' fever in research facilities containing agricultural animals are available.[32]

24.7 BOVINE PETECHIAL FEVER (ONDIRI DISEASE)

Bovine petechial fever is associated with *Ehrlichia ondiri* and occurs in **Kenya,** and possibly **Tanzania,** in cattle grazing thick scrub land or indigenous forest areas at 1500–3000 m altitudes. Characteristically, disease occurs in cattle that break out from fenced pastures and graze the adjacent forest or bushland areas, or when they are grazed on these areas at the end of the dry season.[1]

Bovine petechial fever occurs in **cattle** that have been **recently introduced** to these areas and indigenous cattle appear to acquire resistance. Epidemics occur in cattle imported to infected

areas, last 1–2 months to involve 60–80% of the group with significant losses. Dairy cattle have significant drop in milk yield which persists for several weeks.[1]

Infection can be **experimentally transmitted** to cattle, sheep, goats, wildebeest and impala but natural disease is seen only in cattle.[1,2] Bushbuck (*Tragelaphus scriptus*) are suspected as the reservoir for infection but the vector is not known although epidemiological findings suggest a tick vector of restricted distribution.[3]

The **disease in cattle** is characterized by high fever and the occurrence of petechial hemorrhages in mucous membranes for periods up to 10 days; epistaxis, melena, and hyphema occur in more severely affected animals. Pregnant animals may abort and there is a fall in milk production in lactating animals. Anemia may be severe enough to result in death 3–4 weeks after infection.[1] There is a profound lymphocytopenia by the second day of infection followed by leukopenia and thrombocytopenia. The organism is demonstrable in granulocytes and monocytes during the febrile period but cannot be cultured.

Tetracyclines are effective in treatment. Recovered animals may be latently infected and are immune to reinfection for at least 2 years.

25 Chapter 25 Diseases associated with algae and fungi

25.1 Algal diseases

25.1.1 ALGAL BACTEREMIA

Asymptomatic systemic infections and lymphadenitis associated with the alga *Prototheca zopfii* are extremely rare in cattle[1] and sheep. More common are mastitis and poisoning by algae.

25.1.1.1 REFERENCES

1. H Taniyama, et al.: *Vet Pathol*. **31**, 1994, 123.

25.1.2 PROTOTHECOSIS

Protothecosis is associated with a species of algae belonging to the genus *Prototheca*.[1] *Prototheca wickerhammi* and *P. zopfii* are the only species reported to be pathogenic for animals and man. Single cases have been reported in deer and cats, a few in dogs, and numerous cases in cattle. In cows, all infections have been restricted to the mammary glands and corresponding lymph nodes associated with a long-standing infection and chronic mastitis which is not curable with antimicrobials. One or more cows may be infected in the same herd. Details on mastitis associated with these algae are given in the chapter on Mastitis.

25.1.2.1 REFERENCES

1. AC Pier, et al.: *Med Mycol*. **38**(Suppl 1), 2000, 47.

25.2 Fungal diseases

Identifiable specific infectious mycoses are set out under separate headings below. Other miscellaneous mycotic diseases described in other chapters are:

Pythiosis of nasal mucosal sites, associated with *Basidiobolus ranarum* and *Conidiobolus coronatus*

Guttural pouch mycosis

Rhinosporidiosis associated with *Rhinosporidium seeberi*, *Bipolaris* spp., or *Drechslera* spp. in cattle or *Conidiobolus incongruus* in sheep

Bovine mastitis, usually a sequel to intramammary medication with a contaminated infusion, is a constant occurrence

Fungi also appear in the lists of causes of many diseases associated with mixed infections such as neonatal septicemia, enterocolitis, endocarditis, pneumonia and lymph node abscessation.

25.2.1 ## ASPERGILLOSIS, CANDIDIASIS, ZYGOMYCOSIS, AND MALASSEZIOSIS

Mycoses including aspergillosis, candidiasis and zygomycosis in animals are usually sporadic infections and cause non-specific syndromes because of variation in the organs in which they localize.[1] Peracute, septicemic infections are very rare in adults, except in the occasional case in a parturient female, but are not infrequent in newborn calves and foals.[2]

25.2.1.1 ### ETIOLOGY

Aspergillus and *Candida* spp., and the zygomyces *Absidia corymbifera*, *Rhizopus oryzae*, *Rhizomucor* (*Mucor*) *pusillus* and *Mortierella wolfii* are the common infections which cause systemic mycotic disease. Rare infections occur with *Scopulariopsis* spp. The infections most commonly recorded in bovine mycotic abortion are *Mucor*, *Aspergillus* spp., *Petriellidium* (*Allescheria*) *boydii*, *Candida parapsilosis* and *Mortierella wolfii*.

Yeasts of the genus *Malassezia* inhabit the skin of a variety of mammals and birds and are considered as opportunistic pathogens in animals and man.[3] In a survey of a sample of domestic animals in Spain, *Malassezia* spp. were isolated from 60% of horses, 28% of sheep, 44% of goats, and 58% of cows. The species isolated included: *M. sympodialis*,*M. globosa* and *M. restricta* from sheep.*M. pachydermatis*,*M. fufur*,*M. sympodialis*,*M. obtusa*,*M. globosa*, and *M. restricta* from goats and *M. furfur*, *M. slooffiae*,*M. obtusa*,*M. globsa* and *M. restricta* from horses.[3]

Many different species of fungi have been isolated from the conjunctival sac horses, including *Aspergillus* spp., and other molds such as *Cladosporium*,*Mucor*,*Fusarium*,*Alternaria*, and *Candida* spp.[4]

25.2.1.2

EPIDEMIOLOGY

This is distinctive in fungal diseases; they are not contagious, with the exception of maternal infections which cause the disease in their calves.[5] Each infection arises from the fungal habitat as a saprophyte in organic matter, commonly moldy hay or straw or moist feeds such as beet pulp or brewers' grains which are allowed to go moldy. Risk factors thought to increase the prevalence of oral–gastric mycosis in young pigs and calves are continued and heavy oral dosing with antibiotics and feeding on poorly formulated or administered artificial diets. *Candida glabrata* may have been associated with fungal gastritis and ulcerative colitis in a foal treated with rifampin and spiramycin for rhodococcal bronchopneumonia.[6]

An outbreak of neurological disease in dairy cattle associated with consumption of beer residues contaminated with *Aspergillus clavatus* has been described in Brazil.[7] Beer residues from malting and brewing factories are widely used for dairy cattle feeding in southern Brazil. The affected farm had been feeding beer residues successfully for 15 years.

Fecal samples and intestinal contents of preweaned dairy calves contain yeasts, among which *Candida glabrata* is most common and may be associated with some cases of diarrhea.[8] Feeding calves their dam's milk reduced the shedding of the yeasts compared to commercial milk replacer.

1471

1472

The incidence of mycotic abortions is much greater (up to 30% of all abortions in the herd) in the winter months in housed cows than in any other group, probably because they are exposed to an environment which is likely to be heavily contaminated with spores from moldy hay and ensilage. A correlation also occurs between the abortion rate and a high rainfall in the haymaking season prior to conception.

The increasing incidence of mycotic placentitis leading to abortion may be related to the general use of antibiotic-treated semen in artificial insemination programs but the incidence is no higher in artificially bred cows than in those mated naturally. It is more likely that a transient systemic infection is followed by localization in the pregnant uterus

causing placentitis and abortion. In humans there is an increasing prevalence of systemic mycoses because of the increasing frequency of immunodeficiency states, but prolonged and intensive antibiotic therapy is a commoner precursor in farm animals, especially in aspergillosis.

Microbiological investigations of the guttural pouch of horses affected with mycotic infections have frequently demonstrated the presence of several different *Aspergillus* spp.[9] *Candida krusei* has been isolated from a case of bronchopneumonia in one-year old heifer which was incurable and had to euthanized.[10]

Fungal keratitis (keratomycosis) in horses has been regarded as rare but now account for about 30% of horses diagnosed with keratitis.[4] In the northern hemisphere the disease is more common in the summer and autumn, possibly because climatic and environmental factors favor the proliferation of fungal spores.

Human zygomycosis has been on the increase, and this trend is expected to continue due to increases in the number of immunocompromised hosts The literature on the animal models of *Zygomycosis-Absidia*, *Rhizopus*, *Rhizomucor*, and *Cunninghamella* has been reviewed.[11] Zygomycetes are filamentous fungi which are natural inhabitants of soil and fairly common in the environment. They comprise Mucorales and Entomophthorales.

Mucormycosis due to *Absidia corymbifera* has been described occurring in ponies and 4 of 15 animals died within a few days of onset.[13]

25.2.1.3

PATHOGENESIS

Although inhalation of dust containing fungal elements is an obvious portal of entry for the fungi, with a primary focus developing in a lung, it is generally believed that the more common portal is in the alimentary tract, where the mycosis establishes in a pre-existing abomasal or gastric ulcer or is established in the normal lining of the forestomachs, abomasum and intestines. Hematogenous spread from these foci occurs to all organs, especially splanchnic lymph nodes, liver, lungs and the placenta in pregnant females. Only the placenta is invaded and subsequent fertility is not impaired. Infection of the placenta and uterus can be established by intravenous injection during pregnancy but not by of the injected animals develop placentitis and granulomas in the liver and lungs, and this proportion can be increased by increasing the dose of spores injected.

In **keratomycosis** in horses, traumatic injury to the cornea by plant material, the prolonged use of topical antibiotics may cause a shift in the normal conjunctival flora from Gram-positive to Gram-negative organisms, and the use of topical corticosteroids can all contribute to fungal growth.[4] In temperate climates keratomycosis is normally a chronic disease associated with ocular trauma. Small corneal ulcers may heal, trapping the organisms deep within the stroma, and result in the development of a stromal abscess. Large stromal ulcers may fail to heal and be slowly progressive, and the corneal stroma may melt. Various categories of stromal ulcers occur including: superficial fungal keratitis (punctate lesions of the epithelium and subepithelium stroma); keratomycosis with a surrounding furrow; keratomycosis with a "cake frosting" appearance; and stromal abscess.[4]

Neurological disease in cattle associated with the consumption of beer residues contaminated with *Aspergillus clavatus* is due to the neuromycotoxicosis effect of the mycotoxins of the fungi.[7] Additional information is available in the chapter dealing with mycotoxicoses.

25.2.1.4

CLINICAL FINDINGS

25.2.1.4.1

Pneumonia

Mycotic pneumonia is uncommon in farm animals but occasional cases or outbreaks occur in all species, sometimes with generalization. A high prevalence can be expected in calves and lambs kept indoors in intensive housing units. The pneumonia may be chronic, subacute or acute – a fibrinous pneumonia of very short duration. All forms are fatal and are characterized by mouth-breathing dyspnea, profuse salivation and a mucopurulent nasal discharge and accompanying crusting and erosion. Vesication or ulceration of the muzzle, profuse lacrimal discharge without any apparent eye lesion, abnormal lung sounds and fever are seen and all signs do not improve with antibiotic therapy.

In some cases of mycotic pneumonia in cow associated with *Moreierella wolfii* death occurs within 24 hours after clinical signs of inappetence and lethargy.[13]

Mucormycosis in ponies has been characterized by sudden death, diarrhea, fever, and circling and convulsions. Large ulcers may develop in some cases on the muzzle, nostrils

and lips, and on the knees and hocks. Skin lesions consist of erythematous indurated areas with a central area of necrosis.[12]

25.2.1.4.2

Encephalopathy

An outbreak of encephalopathy has been described in dairy cattle fed beer residue contaminated with *Aspergillus clavatus*.[8] Clinically affected cattle by flaccid paralysis and gait abnormalities. Clinical signs were more pronounced after exercise and included stiff and unsteady gait, knuckling of the fetlocks of the hindlimbs, frequent falling, inability to rise, muscular tremors especially of the head and hindquarters, and drooling. The clinical course varied from 2 days to 2 weeks; most animals died or were euthanized; the population mortality rate of herd was 15%. New cases stopped after the feeding of beer residue was discontinued.

Rhinocerebral zygomycosis has been recorded in a sheep.[14]

25.2.1.4.3

Guttural pouch disease of horses

Guttural pouch disease affects mature horses but it may occur in animals as young as 6 to 12 months of age. The most common clinical findings are mucopurulent nasal discharge (unilateral or bilateral), dysphagia, Horner's syndrome, laryngeal hemiplegia or atrophy of the tongue. The diagnosis is made with endoscopy and biopsies may be taken for histological examination and fungal culture.

25.2.1.4.4

Keratomycosis in horses

Fungal keratitis is normally very painful with marked corneal change accompanied by a severe uveitis, blepharospasm, photophobia and lacrimation.[4] There is corneal ulceration with a “cake frosting” appearance, ulceration with or without furrowing, or stromal abscessation. The duration is commonly several weeks even with treatment. The differential diagnosis of infectious ulcerative keratitis includes: recurrent uveitis, bacterial or viral ulcerative keratitis, stromal abscesses associated with fungi or bacteria.[4]

25.2.1.4.5

Pharyngitis/gastroenteritis

Mycotic pharyngitis and gastroenteritis in pigs and calves results in diarrhea, and, in pigs, vomiting. There is commonly a white pseudomembrane at the back of the pharynx

and extending down the esophagus to the stomach. Cases of mycotic omasitis, rumenitis and enteritis in adult ruminants show anorexia, fever and diarrhea. Mycotic rumenitis secondary to carbohydrate engorgement is a separate issue dealt with elsewhere.

25.2.1.4.6

Abortion

Fungal placentitis resulting in abortion occurs in cows usually at months 6–8 of their pregnancy. Placental lesions are described below and hyphae can be seen on examination of direct smears of the cotyledon or the fetal stomach, preferably the former. A dermatomycosis occurs rarely in the aborted fetal calves, with discrete patches of alopecia, and a raised, grayish, felted covering occurring all over the body. Congenital infection may also occur, granulomatous lesions containing the fungus may be found in the lungs of day-old lambs.

25.2.1.4.7

Mammary aspergillosis

Aspergillar mastitis, associated with *Aspergillus fumigatus*, occurs in ewes causing a severe infection resulting in destruction of the infected mammary tissue.[15]

25.2.1.4.8

Other manifestations

- **Preputial catarrh** accompanied by slowness of service and masturbation has been associated with infection in bulls by an *Absidia* sp. fungus thought to be transmitted at coitus
- **Dermatitis** associated with *Candida* spp. can occur in pigs kept in a damp environment
- **Cutaneous mycotic granulomata**, causing lesions similar to those of cutaneous tuberculosis, occurs rarely in cattle
- Intramammary *Aspergillus fumigatus* infection in dairy ewes has been associated with antibiotic dry therapy.[16] Severe debilitating mastitis was observed and it contamination of the teat ends at the time of administration of the antibiotic was suspected.

25.2.1.5

CLINICAL PATHOLOGY

Sophisticated laboratory techniques are now available to diagnose systemic mycosis and to identify the pathogen. These include immunostaining of tissues[17] and serological methods.[18] All of the following techniques have been used but there is no clearly defined, superior set of tests:

- Polymerase chain reaction
- Murine monoclonal and rabbit polyclonal antibodies in histochemistry
- Immunoblotting
- ELISA of antibodies in serology.

In ewes with Aspergillar mastitis, the detection of antibody by ELISA in sera is a reliable method for the diagnosis.[15]

In mycotic pneumonia, radiodense areas in the lung, representing typical granulomata, are characteristic and transtracheal washes contain many fungal bodies.

In keratomycosis in horses, samples must be taken from the lesions and submitted for culture of fungi on Sabouraud's agar.[4] Deep corneal biopsies may be necessary to confirm the diagnosis.

25.2.1.6

NECROPSY FINDINGS

25.2.1.6.1

Alimentary tract

Lesions in pigs are edema, hemorrhage, and ulceration of the gastric (or abomasal in the case of calves), intestinal and sometimes the esophageal mucosa. Lesions of the forestomachs in adult ruminants include acute hemorrhagic mucosal necrosis.

25.2.1.6.2

Encephalopathy and myopathy

In cattle affected with *Aspergillus clavatus* in beer residue, gross lesions consisted of degeneration and necrosis of large muscle groups of the hindquarters. Histologically, there was degeneration and necrotic neuronal changes in the brainstem and neurons of the ventral horns of the spinal cord.[7]

25.2.1.6.3

Respiratory tract

Lesions include severe fibrinous pneumonia in very acute cases, and multiple discrete granulomata, often appearing as small abscesses, often with necrotic centers giving a superficial resemblance to tuberculosis in the lungs. In lambs the granulomata appear as very small nodules (1–3 mm diameter) and resemble those associated with infestation with *Muellerius capillaris*.

In mycotic pneumonia in a cow associated with *Mortierella wolfii*, the lung was firm, dark red, had bilateral adhesions between the caudal aspects of the lungs and the diaphragm. Histologically, there is severe acute fibrinous bronchopneumonia with multifocal necrosis. Large numbers of non-septate, non-dichotomous, irregular branching hyphae are present in the alveoli.[13]

25.2.1.6.4

Lymph node granulomata

These are a common finding, often in normal animals on the slaughter floor and are seen in the mesenteric, mediastinal and submandibular lymph nodes. These are of importance in the differential diagnosis of tuberculosis.

25.2.1.6.5

Reproductive tract

Placentitis characterized by necrosis of the maternal cotyledons, the adherent necrotic material giving the placental cotyledon the appearance of a soft, yellow, cushion-like structure, and small yellow, raised leathery lesions on the intercotyledonary areas are diagnostic. Corresponding lesions occur on the endometrium, and ringworm-like lesions occur on the fetal skin. Hyphae can be seen on examination of direct smears of cotyledons, fetal stomach and skin. If mycotic abortion is suspected the placental cotyledons offer the best source of material. Every effort should be made to obtain the entire placenta as the infection may be patchy and involve only a few cotyledons. The fungi can be cultured on suitable media.

25.2.1.6.6

Equine mucormycosis

Systemic mucormycosis in a horse due to *Absidia corymbifera* has been described.[12] Pulmonary congestion, pleural hemorrhages and a brain infarct were present.

25.2.1.7

TREATMENT

Treatment of systemic mycoses has been largely by amphotericin and nystatin but the newer azole compounds (enilconazole, fluconazole, itraconazole, ketoconazole) administered orally appear to be highly effective and easy to administer. Any attempt at control of systemic fungal infections is disadvantaged by the lack of a reliable typing system for the causative fungi.

1473

1474

The treatment of keratomycosis in horses is a special topic and the reader should consult the literature in veterinary ophthalmology. Treatment consists of topical antifungal agents, systemic non-steroidal anti-inflammatory agents to control ocular pain, the placement of a lavage system for the regular administration of drugs into the eye, and a consideration of keratectomy and conjunctival graft as necessary.[4]

25.2.2

ASPERGILLOSIS IN HORSES (*ASPERGILLUS* SPP.)

Diseases of horses associated with infection with *Aspergillus* spp. are characterized by either localized infections with slow progression or fulminant systemic or pulmonary disease. Localized infections are of the nasal cavities and paranasal sinuses, eye, reproductive tract including placenta, mediastinum, or guttural pouch. Systemic disease can affect any organ, including brain, liver and kidney, but the most common manifestation is as acute pulmonary disease with or without infection of other tissues.

The causative organism is *Aspergillus* spp. usually *A. fumigatus* but occasionally one of *A. flavus*, *A. deflectus*, *A. nidulans*, *A. niger* or *A. clavulatus*.[1] Aspergilli reproduce both sexually and asexually and hence are classified as dimorphic fungi. Asexual reproduction is by production of conidiophores and conidia. The organism is ubiquitous in organic material and infections are opportunistic and associated with heavy contamination with the organism or decreased host defenses, although obvious risk factors are not always identified. Because its ubiquitous, the organism is often recovered from tracheal aspirates performed using

contaminated equipment in horses with mild signs suggestive of non-infectious respiratory disease, such as heaves. In this instance recovery of the organism is of no clinical importance.

Risk factors for development of aspergillosis include heavy contamination with conidia, and decreased host resistance, such as in horses with immune suppression associated with myeloproliferative disease (lymphoma), enterocolitis, and administration of immunosuppressive drugs such as corticosteroids.[2–4] Specific risk factors for guttural pouch mycosis and infections of the nasal cavity or paranasal sinuses have not been identified with the exception of an association between surgical resection of ethmoidal hematoma and subsequent nasal aspergillosis.[5] Keratomycosis associated with *Aspergillus* spp. is usually secondary to other ocular lesions, or ocular instillation of immunosuppressant drugs. The ocular disease can also occur in horses housed in barns with heavy contamination with *Aspergillus* spp. Systemic or pulmonary aspergillosis is commonly associated with enterocolitis or administration of immunosuppressive drugs in adult horses.[2,6]

Aspergillus spp. causes both localized and systemic disease in horses. Localized diseases include **guttural pouch mycosis**, which is discussed in detail elsewhere in this text. Fungal granulomas in the **paranasal sinuses** or **nasal passages** of horses are caused by a number of organisms, including *Cryptococcus neoformans*, and rarely by *Aspergillus* spp.[7,8] The disease is evident as nasal discharge that is usually unilateral, distortion of the contour of the head over the affected sinus, and lesions detectable on endoscopic examination of the nasal passages. Radiography can reveal the presence of a mass in the paranasal sinuses or nasal cavity associated with lysis and proliferation of bone. There is hyperfibrinogenemia and leukocytosis.

Keratomycosis due to *Aspergillus* spp. infection is infrequent in horses. The disease is characterized by blepharospasm, photophobia, epiphora, and corneal ulceration and opacity. *Aspergillus* spp. infections of the reproductive tract include mycotic **placentitis** and abortion and mycotic **endometritis**.[9]

Systemic aspergillosis, including aspergillus **pneumonia**, is a severe disease usually evident as acute death without localizing signs in horses with other preexisting systemic disease, such as enterocolitis, or those receiving immunosuppressive drugs.[6,9] Horses with aspergillus pneumonia often have a very brief clinical course once signs of respiratory disease develop. Most commonly, horses with pulmonary aspergillosis die without signs of respiratory disease. Signs of pulmonary aspergillosis include fever, tachypnea, crackles and

wheezes on thoracic auscultation, epistaxis, and frothy nasal discharge. Radiography reveals diffuse, miliary, nodule interstitial pneumonia. Ultrasonographic examination demonstrates numerous small intrapulmonary masses adjacent to the pleural surface. Affected horses have hyperfibrinogenemia and leukocytosis at the time of development of the disease, but usually have had neutropenia as a result of the enterocolitis. *Aspergillus* spp. can be isolated from tracheal aspirates of affected horses. The prognosis is very poor.

Disseminated aspergillosis has a variety of manifestations but is always a severe disease with a brief clinical course. Affected horses often have severe depression and can have signs of brain disease as a result of mycotic vasculitis and encephalitis.[11] The prognosis is very poor.

Aspergillus spp. is also associated with development of granulomas in the **mediastinum** of horses without apparent predisposing factors.[12–14] Affected horses have progressively worsening respiratory distress, cough, fever, and occasional nasal discharge. Horner's syndrome can develop if the mass encroaches on the vagosympathetic trunk within the thorax.[14] The mass is evident on radiographic examination of the thorax. Cultures of tracheal aspirates yields *Aspergillus* spp. Affected horses have neutrophilia, hyperfibrinogenemia, hyperglobulinemia and mild anemia.

Definitive diagnosis of the disease is based on demonstration of organisms within lesions, either by histologic examination or by culture, and by demonstration of high titers in serum of antibodies specific for *Aspergillus* spp. Antemortem demonstration of high concentrations of antibodies to *Aspergillus* spp. provides persuasive, but not definitive, evidence of infection. Both agar gel immunodiffusion assays and ELISA assays are available. These assays might not be useful in immunocompromised animals or in those with fulminant disease.

Acute lesions are characterized by purulent, necrotizing inflammation.[1,2] Chronic lesions are granulomas that contain macrophages, neutrophils and giant cells.[1] Pulmonary lesions are characterized by an acute necrohemorrhagic alveolitis.[2] Organisms morphologically consistent with *Aspergillus* spp. are detected in the lesions as fungal hyphae, although these must be differentiated from *Pseudoallescheria boydii* or *Fusarium* spp.[1] Reagents for immunofluorescent detection of *Aspergillus* spp. in lesions are available and useful in confirming the diagnosis.[1]

Treatment of systemic or pulmonary disease is usually unrewarding. Localized disease can be treated by surgical resection and administration of antifungal agents. Antifungal agents reported to be effective in treatment of localized disease associated with *Aspergillus* spp. include itraconazole (3 mg/kg q 12 h, PO for 3–5 months).[8] Topical treatment with enilconazole (10 mg/mL of solution) after surgical resection resulted in resolution of aspergillosis of the frontal sinus of a horse.[7] Topical administration of natamycin (25 mg) was used for varying periods of time to treat mycotic rhinitis in three horses.[5]

Amphotericin is likely effective against *Aspergillus* spp. and is cheaper than the azole class of drugs, but is potentially nephrotoxic and must be administered intravenously. Fluconazole is not effective against the filamentous fungi, including *Aspergillus* spp.

1474

1475

There are no specific control measures or means of preventing disease associated with *Aspergillus* spp.

25.2.3 COCCIDIOIDOMYCOSIS

25.2.3.1 ETIOLOGY

Coccidioides immitis is associated with the disease in all species including humans.

25.2.3.2 EPIDEMIOLOGY

Coccidioidomycosis is a comparatively benign disease of farm animals, usually causing no apparent illness.[1] Sporadic cases are recorded in all species but are most common in dogs and in cattle and to a much less extent in pigs, sheep, and horses. Pulmonary coccidiodomycosis has been described in a 13-day-old foal.[2]

The disease is enzootic in the south-western United States and up to 20% of cattle finished in feedlots in the area may harbor the fungus. The incidence of the disease in humans in the area provides a major problem in public health. It is not contagious, infection occurring by inhalation of spores of the fungus which grows in the soil, and possibly by ingestion and through cutaneous abrasions.

25.2.3.3 CLINICAL FINDINGS

In horses[3] findings include weight lossup to severe emaciation, a fluctuating temperature, persistent cough, muscle pain, and superficial abscesses, often recurring, and most commonly in the pectoral area. Increased lung sounds, wheezing, and dullness are audible over the ventral chest. Other signs include edema of the legs, anemia and intermittent colic due to internal abscesses and peritoneal adhesions. Liver rupture may cause death. Affected sheep show fever and abscesses in peripheral lymph nodes.

25.2.3.4 CLINICAL PATHOLOGY

A leukocytosis is usual. An extract of the fungus, coccidioidin, has been used in an intradermal sensitivity test, and complement fixation and immunodiffusion tests are used diagnostically in humans.

25.2.3.5

NECROPSY FINDINGS

The lesions produced in cattle and pigs are granulomatous, contain a cream-colored pus, and are sometimes calcified and are found in the bronchial, mediastinal and rarely the mesenteric, pharyngeal and submaxillary lymph nodes and in 'the lungs. In a neonatal foal, the lungs were diffusely infiltrated with a miliary pattern of multiple, coalescing, pale tan to red, irregularly shaped, slightly raised, firm foci, 0.1 to 0.5 cm in diameter.[2]

25.2.3.5.1

DIFFERENTIAL DIAGNOSIS

Microscopic or cultural examination may be used to identify the disease. Isolation of the organism is preferred as evidence because of the non-specificity of coccidioidis.

25.2.3.5.1.1

Differential diagnosis list:

- Cattle and pigs – tuberculosis
- Sheep and goats – caseous lymphadenitis.

25.2.3.6

TREATMENT

No effective treatment is available. Because infection occurs by the inhalation of soil-borne spores, control of dust in feedlots may help to prevent the spread of the disease. Dust control is a major factor in prevention of human coccidioidomycosis because there is no vaccine or effective therapeutic agent available and the eradication of *C. immitis* from the soil is not practicable.

3. EL Ziemer, et al.: *J Am Vet Med Assoc*. **201**, 1992, 910.

25.2.4

HISTOPLASMOSIS

Histoplasmosis, associated with infection with *Histoplasma capsulatum*, is a rare systemic mycosis in farm animals, with a high prevalence in specific geographic localities, e.g. the Mississippi river system. Cases have been recorded in horses, cattle and pigs. The fungus is

able to survive for periods as long as 4 months in soil and water. Infection occurs by the inhalation of contaminated dust, and primary invasion usually takes place in the lung. The disease may spread from animals to humans. Attempts at experimental infection in cattle, sheep, horses and pigs have resulted in non-fatal infections, unless the agent is given intravenously, but the test animals become positive to the histoplasmin cutaneous sensitivity test.

Clinical syndromes vary greatly and include pneumonia, with dyspnea and nasal discharge, hepatic insufficiency with jaundice and anasarca, placentitis with abortion, and widespread lesions in neonates, especially foals.[1] As a diagnostic aid for herd or area the histoplasmin skin test appears to be satisfactory. Keratitis due to *Histoplasma* spp. has been described.[2] Histoplasmosis may be secondary to Yersiniosis in the horse.[3]

Necropsy lesions are as variable as the clinical syndrome and include gross hepatic enlargement containing necrotic foci, pulmonary consolidation and granulomatous pneumonia, and enlargement of splanchnic lymph nodes. Aggregation of the fungal bodies in lymphoid tissue and other tissues in which large numbers of phagocytes are in residence is characteristic of the disease; the lesions consist of groups of macrophages packed with fungal cells.

The disease associated with infection with *H. farciminosum* is dealt with under the heading of epizootic lymphangitis.

25.2.5

RHINOSPORIDIOSIS

Rhinosporidiosis is a chronic disease of the nasal mucosa in cattle and horses causing formation of large polyps in the posterior nares and interference with respiration. The causative fungus, *Rhinosporidium seeberi*, can be found in large sporangia in the polyps.

A related condition in cattle also thought to be caused by an unidentified fungus, similar to *Rhinosporidium* spp., is nasal granuloma, in which the lesions are small (0.5–2.0 cm diameter) mucosal nodules in the anterior third of the nasal cavity. Histologically there is a

marked eosinophilic reaction and yeast-like bodies are present in cells or free in the tissue spaces. Clinical signs include severe dyspnea with loud stertor and a mucopurulent or blood-stained nasal discharge. A high incidence of the disease may occur on some farms and in particular areas

Other diseases with similar clinical profiles include nasal obstruction associated with the blood fluke, *Schistosoma nasalis* and chronic allergic rhinitis.

25.2.6 CRYPTOCOCCOSIS (EUROPEAN BLASTOMYCOSIS, TORULOSIS)

Infection with the yeast *Cryptococcus neoformans* occurs in most species, either as a generalized disease or as a granulomatous meningoencephalitis. Nervous system involvement is manifested by stiffness, hyperesthesia, blindness or incoordination. Systemic involvement includes cases of myxomatous lesions of nasal mucosa, pulmonary abscess or pneumonia, jejunal granuloma, lymphadenitis, placentitis with abortion and systemic involvement in the fetus. *C. neoformans* is listed as a cause of bovine mastitis. In human medicine an accurate serological test is used in diagnosis.

1475 1476

25.2.7 NORTH AMERICAN BLASTOMYCOSIS

The fungus associated with this important zoonosis is *Blastomyces dermatitidis*. It is relatively common in dogs but appears to have been recorded only once in large animals causing perineal abscessation, emaciation and death in a horse. In humans and dogs the characteristic lesions are cutaneous or pulmonary granulomata.

25.3 Dermatomycoses

25.3.1 RINGWORM

25.3.1.1 Synopsis

Invasion of cutaneous keratinized epithelial cells and hair fibers by dermatophytes.

25.3.1.1.1 Etiology

Trichophyton, *Microsporum* spp. fungi

25.3.1.1.2

Epidemiology

Carrier animals are the source; spread is via direct contact or contact with infected inanimate objects. Housed animals most susceptible

25.3.1.1.3

Clinical signs

Circumscribed areas of hairless skin, thick gray crumbly crusts (cattle), or shiny, bald areas (horse), heavy pityriasis; common locations where infection likely to contact e.g. neck, sides

25.3.1.1.4

Clinical pathology

Spores and mycelia in skin scraping, or in culture

25.3.1.1.5

Necropsy lesions

Mycelia identifiable in skin sections

25.3.1.1.6

Diagnostic confirmation

Lab typing of fungus in scraping or tissue

25.3.1.1.7

Treatment

Spontaneous recovery usual. Topical fungistat, systemic griseofulvin, parenteral iodide all used. Vaccination widely used in European countries.

25.3.1.2

ETIOLOGY

The listed associated fungi which grow on the hair, skin or both are:

- **Horse:** *Trichophyton equinum*,*Tr. quinckeanum*,*Tr. mentagrophytes*,*Tr. verrucosum*,*Microsporum equinum*,*M. gypseum*
- **Donkey:** *Tr. mentagrophytes*, *Tr. verrucosum*
- Cattle:*Tr. verrucosum*,*Tr. mentagrophytes*,*Tr. megninii*,*Tr. verrucosum* var.*album*,*Tr. verrucosum* var.*discoides*

- Pig: *Tr. mentagrophytes*,*Tr. rubrum*,*Tr. verrucosum* var.*discoides*,*M. canis*, *M. nanum*
- **Sheep:** *Tr. verrucosum* var.*ochraceum*,*Tr. quinckeanum*,*Tr. mentagrophytes*,*Tr. gypseum* ("club lamb fungus" in show lambs in the US), *M. canis*
- **Goat:** *Tr. verrucosum*.

Uncommon dermatophytes also found in skin lesions in farm animals and horses are: *M. gypseum* and *Keratinomyces allejoi* in horses; *Scopulariopsis brevicaulis* in cattle; *M. nanum* in adult pigs, in which it is most common, and in which the lesions are often so mild as to go unnoticed by the farmer; *Alternaria alternata* in horses, goats, pigs, sheep and cattle.

A rare but similar disease is tinea versicolor, a fungal dermatomycosis associated with *Malassezia furfur* (syn. *Pityrosporum orbiculare*) on the teats of goats. The lesions are circular, discrete, slightly thickened and scaly at the edges but not painful. They are characterized by an alteration in the color of the surrounding skin, either darker or lighter. The infection persists on a patient for at least a year and in a flock for a longer period. Hyphae are distinguishable in sections of the lesions.

25.3.1.3 ## EPIDEMIOLOGY

25.3.1.3.1 ### Occurrence, source of infection and transmission

Ringworm occurs in all animal species in all countries but more commonly where animals are accommodated in dense groups, especially indoors.

Direct contact with infected animals is the common method of spread of ringworm, but indirect contact with inanimate objects, particularly bedding, harness, grooming kits and horse blankets, is probably more important. Spores can exist on the skin without causing lesions, and up to 20% of normal animals in an infected group will act as "carrier animals". Premises and harness may remain infective for long periods because fungal spores remain viable for years provided they are kept dry and cool. Moderate heat and desiccation destroy them.

A dermatophytosis in lambs in the United States, called "**club lamb fungus**" affects lambs during lamb show season.[1] Approximately one-third of families reported children

or owners involved in showing these lambs developed skin lesions consistent with dermatophytosis.

Ringworm in yearling horses can interfere with training causing economic losses because of the isolation required to prevent spread of infection to other horses and humans and to decrease environmental contamination.[2]

25.3.1.3.2 Risk factors

25.3.1.3.2.1 Pathogen factors

M. gypseum, *K. allejoi* and *M. nanum* are soil saprophytes and the reasons for their assumption of pathogenicity are not understood.

25.3.1.3.2.2 Environment and host factors

A high incidence of clinical cases in the winter and of spontaneous recovery in the spring is common, but outbreaks also occur during the summer months, so that close confinement and possibly nutrition seem to be more important in the spread of the disease than other environmental factors such as temperature and sunlight. Humidity is known to be important, a high humidity being conducive to multiplication of the fungus. In calf-rearing and vealing units the prevalence is greater in units which continuously add or remove calves from the stock; an “all-in all-out” program is less conducive to spread of the disease.

Animal susceptibility is determined largely by immunological status, so that young animals are most susceptible.

25.3.1.3.3 Zoonotic considerations and economic importance

Spread between species occurs readily and in rural areas 80% of human ringworm may derive from animals. *Trichophyton* spp. infections are commonly contracted from horses and cattle and *M. canis* infections from dogs. Ringworm of animal origin affects adult humans as well as children and diagnosis and treatment are often very difficult. Between 1962 and 1994, 32 isolates of *Trichophyton verrucosum* from cases tinea corporis, tinea faciei and tinea captis were identified in Victoria, Australia.[3] Infected patients were mainly from rural areas and frequently had a history of contact with cattle. Isolates

included those from dairy and beef cattle farmers, children who lived on dairy or cattle farms or in a dairy farming area, a slaughterhouse employee and a veterinarian.

Injury to affected animals is of a minor nature but sufficient damage to hides occurs to warrant some attempt at control of the disease.

25.3.1.4

PATHOGENESIS

Ringworm fungi chiefly attack keratinized tissues, particularly the stratum corneum and hair fibers, resulting in autolysis of the fiber structure, breaking off of the hair, and alopecia. Exudation from invaded epithelial layers, epithelial debris and fungal hyphae produce the dry crusts which are characteristic of the disease. The lesions progress if suitable environmental conditions for mycelial growth exist, including a warm humid atmosphere, and a slightly alkaline pH of the skin. Ringworm fungi are all strict aerobes and the fungi die out under the crust in the center of most lesions, leaving only the periphery active. It is this mode of growth which produces the centrifugal progression and the characteristic ring form of the lesions.

1476

1477

The significance of skin pH in the development of ringworm is widely known. The susceptibility of humans to ringworm infection is much greater before puberty than afterwards when the skin pH falls from about 6.5 to about 4.0. This change is largely due to excretion of fatty acids in the sebum and these fatty acids are often highly fungistatic. Calves are more commonly infected than adult cattle but whether this is due to increased susceptibility in calves or the development of immunity in adults has not been determined.

There is some experimental evidence that traumatic injury of the skin is an important factor for the development of ringworm lesions in calves.[4] Different numbers of microconidia of *Trichophyton verrucosum* are required to induce ringworm depending on the degree of shearing of the hair and scarification of the skin.

Secondary bacterial invasion of hair follicles is common. The period after experimental infection before distinct lesions appear is about 4 weeks in calves, but considerably less in horses. Spontaneous recovery occurs in calves in 2–4 months, the duration and severity of the disease often depending upon the nutritional status of the host. A resistance to reinfection occurs after recovery from experimental or natural infection even though a local mycotic dermatitis may occur at the reinfection site. The immunity is specific to the fungal species concerned, and in horses lasts up to 2 years.

25.3.1.5 CLINICAL FINDINGS

25.3.1.5.1 Cattle

The typical lesion is a heavy, gray-white crust raised perceptibly above the skin. The lesions are roughly circular and about 3 cm in diameter. In the early stages the surface below the crust is moist, in older lesions the scab becomes detached and pityriasis and alopecia may be the only obvious abnormalities. Lesions are most commonly found on the neck, head and perineum but a general distribution over the entire body may occur, particularly in calves, and in severe cases the lesions may coalesce. Itching does not occur and secondary acne is unusual.

25.3.1.5.2 Horses

The lesions may be superficial or deep. Superficial infections are more common. Lesions due to *Tr. equinum* commence as round patches of raised hair and soreness of the lesions to touch. This stage is followed about 7 days later by matting of the hair, which becomes detached leaving a bald, gray, shining area about 3 cm in diameter. Fine scabs appear and recovery with regrowth of hair commences in 25–30 days. Heavier scabs and larger lesions are usually due to rubbing by harness. Lesions associated with *M. gypseum* are smaller, about 10 mm in diameter, and are manifested either by the development of thick crusts, or more generally a diffuse moth-eaten appearance with desquamation and alopecia. Less commonly, deeper structures are infected through the hair follicles, causing small foci of inflammation and suppuration. A small scab forms over the follicle and the hair is lost but extensive alopecia and crust formation do not occur. Some irritation and itching may be caused by this type. The distribution of lesions in the horse differs from that in cows, lesions usually appearing first on the axillary girth area and spreading generally over the trunk and over the rump and may spread to the neck, head and limbs.

25.3.1.5.3 Pigs

Regular ringworm lesions in pigs develop as a centrifugally progressing ring of inflammation surrounding a scabby, alopecic center. The lesion produced by *M. nanum* is different – there is no pruritus or alopecia and cutaneous reaction is minimal, but the centrifugal enlargement of each lesion may cause it to reach an enormous size.

Superficial, dry, brown crusts cover the affected area but arenot obviously raised except at the edges in some cases. The crusts are formed of flakes or dust composed of epithelial debris. Most lesions occur on the back and sides. Spontaneous recovery does not occur in adult pigs.

25.3.1.5.4

Sheep

In sheep the lesions occur on the head, rarely in the fleeced areas and, although they usually disappear in 4–5 weeks, the disease may persist in the flock for some months. The lesions are discrete, round, almost bald patches covered with a grayish crust. Similar lesions occur in goats, but they are distributed generally over all parts of the body. The exception to this description is a new ringworm associated with an unidentified *Trichophyton* which has appeared in sheep in western States of USA plus Georgia and Kentucky since 1989. Lesions occur extensively in fleeced areas and are characterized by shedding of the wool staple and exudation from the skin surface. Serious spread of the infection to human attendants occurs.[5]

Outbreaks of ringworm in sheep flocks associated with *Trichophyton verrucosum* have been reported in Scotland.[6] The outbreaks have been unusual because of the high morbidity rates and persistence of active lesions for up to 6 months. The presence of ringworm lesions precluded the sale of rams in affected flocks.

In “club lamb fungus” in show lambs in the US, gross lesions typical of ovine dermatophytosis were located on all parts of the body, and consisted of circular areas of matted wool, crusts and discoloration.

25.3.1.6

CLINICAL PATHOLOGY

Laboratory diagnosis depends upon the demonstration of spores and mycelia in skin scrapings and in culture. Skin scrapings should be made after defatting the skin with ether or alcohol and gently warming the scraping in a 20% solution of either potassium or sodium hydroxide. Spores are the diagnostic feature and appear as round or polyhedral, highly refractive bodies in chains (*Trichophyton* spp.) or mosaics (*Microsporum* spp.) in hair follicles, epithelial scales, and in or on the surface of hair fibers. A hair perforation test, which measures the capacity of a fungal isolate to perforate human hair fibers in the laboratory, is used in the differentiation of dermatophytic species.

Examination of the skin of infected animals to detect the fluorescence associated with some fungal infections can also be a useful clinical aid but many trichophyton fungi do not fluoresce, whereas petroleum jelly and other oily skin dressings may do so. Fungal hyphae in tissues can be identified, even down to the genus, by the use of immunofluorescent staining. The technique was devised for use on necropsy material but should have application for biopsy material and scrapings. Specimens to be sent for laboratory examination should be packed in envelopes, as airtight jars and cans favor the growth of non-pathogenic fungi.

1477

1478

25.3.1.6.1

DIFFERENTIAL DIAGNOSIS

The diagnosis of ringworm depends on evidence of infectivity, the appearance of characteristic lesions and the presence of fungal mycelia and spores. Diagnostic confirmation is by demonstration of fungal elements in a scraping or biopsy.

The differential diagnosis list of ringworm which may be confused with diseases with similar clinical profiles.

25.3.1.6.1.1

Cattle

- Mycotic dermatitis, which has tenacious scabs which cover a raw area of skin
- Inherited parakeratosis, characterized by tenacious thick crusts which respond quickly and completely to dietary supplementation with zinc
- Sarcoptic mange, in which mites can be demonstrated in scrapings; there is intense pruritus and a quick response to standard insecticides
- Psoroptic mange, identifiable by the presence of mites in scrapings, pruritus, occurrence in housed cattle, and the location of the lesions over the hindquarter

25.3.1.6.1.2

Pigs

- Pityriasis rosea, in which no mites can be demonstrated and the disease is limited to a particular age group
- Exudative epidermitis has extensive lesions with a characteristic greasy covering

- Tyrogliphosis is self-limiting, associated with a new source of grain, and characterized by pruritus.
- Sarcoptic mange, identifiable by the mites in scrapings, the intense pruritus and the prompt response to treatment with insecticide

25.3.1.6.1.3

Horses

- Mycotic dermatitis which is limited in its distribution to the back of the horse, and *Dermatonomus congolensis* can be cultured
- Queensland itch diagnosable on its occurrence only in summer, only along the back, and the associated intense pruritus
- Other equine dermatitides.

25.3.1.7

TREATMENT

Many recorded cures are no doubt dueto strategic treatment just prior to spontaneous recovery, but treatment is widely practised, and recommended because it greatly reduces contamination of the environment by infected animals. Local or systemic treatments are used, the latter when lesions are widespread.

25.3.1.7.1

Local application

The crusts should be removed by scraping or brushing with a soft wire brush and burned; the medicament should be brushed or rubbed in vigorously. Suitable topical applications include a weak solution of iodine, Whitfield's ointment, 10% ammoniated mercury ointment, and solutions of quaternary ammonium compounds (1:200–1:1000), propionic and undecylenic acid ointments, solutions of 0.25% hexadecamethylene-1, 16-bis-isoquinolinium chloride(Tinevet), Hexetidine (bis-1,3 beta-ethylhexyl-5 methyl-5-amino-hexahydropyrimidine) borotannic complex, thiabendazole 1–5% ointment, the antibiotics (natamycin and nanomycin A), povidone-iodine, thiabendazole and captan ointments, and ointments containing one of the azole compounds such as imidazole or miconazole. These topical treatments are probably of greater value in the early stages of an outbreak when the lesions are small and few in number.

25.3.1.7.2

Sprays, washes

When infection in a group is widespread, washes or sprays which can be applied over the entire body surface of all animals are used, although the efficacy of the preparations is less than that of ointments, and daily application for at least 5 days is required. Sprays have a big advantage if prophylactic treatment of all in-contact animals is recommended. Examples are agricultural Bordeaux mixture, 5% lime sulfur (20% w/v polysulfides diluted 1:20), captan (N-(trichloromethylthio)-cyclohex-4-ene-1,2-dicarboxamide) 3%, N-trichloromethylthio-tetrahydrophthalimide, iodofors, 0.5% sodium hypochlorite, natamycin (100 ppm).

25.3.1.7.3

Systemic treatment

Systemic treatments recommended for use in farm animals include the intravenous injection of sodium iodide (1 g/14 kg body weight) as a 10% solution repeated on several occasions, and, if the high cost of the treatment can be overlooked, the oral administration of griseofulvin.

Spontaneous recovery is common in individual animals and careful appraisal of results in clinical trials is necessary. Many farmers overtreat their animals with irritant preparations administered daily for long periods. A crusty dermatitis, or even a neoplastic acanthosis may result.

25.3.1.8

CONTROL

25.3.1.8.1

Hygiene

Failure to control an outbreak of ringworm is usually due to the widespread contamination of the environment before treatment is attempted. Isolation and treatment of infected animals, the provision of separate grooming tools, horse blankets and feeding utensils, and disinfection of these items after use on affected animals are necessary if the disease is to be controlled. Cleaning and disinfection of stables with a commercial detergent or a strong solution (2.5–5%) of phenolic disinfectant, 5% lime sulfur, 5% formalin, 3% captan or 5% sodium hypochlorite is advisable where practicable. Good results are also claimed for the disinfection of buildings with a spray containing 2.0% formaldehyde and 1.0% caustic soda.

25.3.1.8.2

Vaccination

Vaccination has achieved a great deal of success in preventing infection in cattle and horses[7] in most countries of Europe and Scandinavia. Vaccines include those containing highly immunogenic, non-virulent strains, or attenuated[8] strains of fungi, or those killed vaccines containing specific fractions of mycelia. Vaccination of all animals in the group is recommended, and isolation and treatment of infected animals and disinfection of premises and gear must be carried out at the same time.

The vaccine is almost totally without side effects except for very rare deaths due to anaphylaxis, apparently related to keeping reconstituted vaccine for too long a period. Existing cases of ringworm may be exacerbated.

25.3.1.8.3

Nutrition

Although ringworm occurs in well-nourished as well as poorly fed animals, there does seem to be a tendency for the latter to become infected more readily and to develop more extensive lesions. Supplementation of the diet, particularly with vitamin A to young housed animals, should be encouraged as a preventive measure.

25.3.2

EPIZOOTIC LYMPHANGITIS (PSEUDOGLANDERS, EQUINE BLASTOMYCOSIS, EQUINE HISTOPLASMOSIS)

25.3.2.1

Synopsis

25.3.2.1.1

Etiology

Histoplasma capsulatum var. farciminosum, a fungus

25.3.2.1.2

Epidemiology

Epizootic disease of low mortality of horses in Asia, Africa and the Mediterranean

25.3.2.1.3

Clinical signs

Nodules, lymphadenopathy and lymphangitis usually of the hindlimbs. Nodules discharge creamy pus. Conjunctivitis and pneumonia may occur. Spontaneous resolution, after long course, is usual

25.3.2.1.4

Clinical pathology

Organism in pus, fluorescent antibody test. Histofarcin skin test

25.3.2.1.5

Lesions

Lymphangitis, lymphadenitis Differential diagnosis Glanders (farcy), ulcerative lymphangitis, sporotrichiosis

25.3.2.1.6

Diagnostic confirmation

Demonstration of organism in pus. Clinical characteristics of the disease

25.3.2.1.7

Treatment

Parenteral iodides. Amphotericin

25.3.2.1.8

Control

Hygiene, slaughter, vaccination

25.3.2.2

ETIOLOGY

The cause is a fungus, *Histoplasma capsulatum* var. *farciminosum*, a dimorphic fungal soil saprophyte. The organism has also been classified by the genus name *Zymonema*, *Cryptococcus*, *Saccharomyces*, or *Blastomyces*.

The disease is listed by the OIE, to which it is notifiable.

25.3.2.3

EPIDEMIOLOGY

The disease occurs as outbreaks inhorses, donkeys and mules in parts of Iran, Asia, India, Northern Africa, and the Mediterranean littoral. Most outbreaks occur in autumn and winter or when large numbers of horses are gathered together for military or other purposes. The disease was detected in 1.0 to 19% of horses in Ethiopia over a 6-month period.[1,2] The mortality rate is 10–15%, but the course is prolonged. Cattle and camels are rarely affected.

Fungal spores are carried from infected animals by direct contact or on bedding, grooming utensils, horse blankets or harness, and gain entry through abrasions, usually on the lower limbs. A saprophytic stage in the soil has been suggested to account for the difficulty experienced in eradicating the disease. The organism has been isolated from the alimentary tract of biting flies and they may play a role in the transmission of the disease.

25.3.2.3.1

Zoonotic potential

Infection is reported in humans.[3]

25.3.2.4

PATHOGENESIS

After gaining entry through wounds, the fungus invades subcutaneous tissue, sets up a local granuloma or ulcer and spreads along the lymphatic vessels. The ocular form of the disease results from inoculation of the organism into the eye, likely by biting flies.

25.3.2.5

CLINICAL FINDINGS

The disease is primarily an ulcerating, suppurative, pyogranulomatous dermatitis and, in most cases, lymphangitis.[4] An ocular form of the disease is characterised by an ulcerating conjunctivitis.

In the **cutaneous form** of the disease an indolent ulcer develops at the portal of entry, making its appearance several weeks to 3 months after infection occurs. A spreading dermatitis and lymphangitis, evident as corded lymphatics with intermittent nodules, develops. Nodules rupture, discharging a thick creamy pus. Local lymph nodes also enlarge and can rupture. Thickening of the skin in the area and general swelling of the whole limb are common. The lesions are quite painless.

The lesions usually develop on the limbs, particularly about the hocks, but may also be present on the back, sides, neck, vulva and scrotum. Occasionally lesions appear on the nasal mucosa just inside the nostrils and do not involve the nasal septum. Ocular involvement is manifested by keratitis and conjunctivitis. Sinusitis and pneumonia occur in other forms of the disease.

The disease is chronic, persisting for 3–12 months. Spontaneous recovery occurs and immunity is solid after an attack but many animals are destroyed because of the chronic nature of the disease.

25.3.2.6

CLINICAL PATHOLOGY

Gram-positive, yeast-like cells, with a characteristic double-walled capsule, are easily found in discharges. The organisms are located both extracellularly and intracellularly in giant cells and macrophages. The agent can be cultured on special media but the fungus

dies quickly in specimens unless these are collected in antibiotic solutions, refrigerated and cultured promptly. The specimen should be collected into a solution containing 500 units/mL penicillin.

The mallein test is negative but a sterile filtrate of a culture of *H. capsulatum* var.*farciminosum* has been used in a cutaneous sensitivity test[5] and several serological tests, including a fluorescent antibody test,[6] are available. Antibodies to *H. capsulatum* var.*farciminosum* are detectable in serum before or at the time of development of lesions.[4]

25.3.2.7

NECROPSY FINDINGS

Lesions are usually confined to the skin, subcutaneous tissues, and lymph vessels and nodes. In some cases granulomatous lesions may be found in the lungs, liver and spleen. Histologically, the lesion is quite characteristic and consists of pyogranulomatous inflammation with fibroplasia. Langerhans giant cells are common. The presence of numerous organisms, some of which show budding, in both intra- and extracellularly in tissue sections stained with H&E, Periodic acid – Schiff reaction and Gomori methenamine–silver stain is of diagnostic value.[4]

25.3.2.7.1

DIFFERENTIAL DIAGNOSIS

See Table 22.3.

- Glanders (*Burkholderia mallei*
- Ulcerative lymphangitis (*Corynbacterium pseudotuberculosis*)
- Sporotrichosis (*Sporothrix schenckii*)
- Histoplasmosis (*Histoplasma capsulatum*)

25.3.2.8

TREATMENT AND CONTROL

Many treatments have been tried, largely without success. Parenteral iodides have been reported as effective in some cases as has amphotericin. Sodium iodide is administered as a 10% solution at a dose of 1 mL per 5 kg intravenously once weekly for 4 weeks.[7] Amphotericin is administered at a dose of 0.2 mg/kg body weight every 48 hours for 3 treatments.

Outbreaks in uninfected areas are probably best controlled by **slaughter of affected animals**. In enzootic areas severe cases should be destroyed andless severe cases kept in strict quarantine while undergoing treatment. All infected bedding, harness and utensils should be destroyed or vigorously disinfected. Formalinized aluminum hydroxide adsorbed, and heat-attenuated vaccines[8] have been widely used, apparently with success.

25.3.3 SPOROTRICHOSIS

Sporotrichosis is a contagious disease of horses, cats, cattle and humans characterized by the development of **cutaneous nodules and ulcers** on the limbs that may be accompanied by lymphangitis.

25.3.3.1 ETIOLOGY

Sporotrichum schenckii (*Sporothrix beurmanii*, *S. schenckii*, *S. equi*), is a Gram-positive dimorphic fungus that forms single-walled spores.[1] The organism survives in a mycelial phase on living or decaying plant material but changes to a yeast phase when it enters a mammalian body through a puncture wound or bite.

25.3.3.2

EPIDEMIOLOGY

The disease is reported to occur in Europe, India and the United States and likely occurs throughout the world. The host range includes humans, horses, cattle, cats, camels, mice, rats, and chimpanzees.[1] Economic loss caused by sporotrichosis is not great because the disease spreads slowly, the mortality rate is low, and treatment is effective. Outbreaks of sporotrichosis in dairy cattle caused reduced milk production.[2]

1479

1480

The causative agent persists in organic matter, and contamination of cutaneous wounds can occur either by contact with discharges from infected animals, or from contaminated surroundings. The disease is readily spread from affected cats to humans.[3] Transmission from horses to humans has not been reported.

25.3.3.2.1

Pathogenesis, clinical findings and clinical pathology

Local invasion through wounds results in the development of abscesses and discharging ulcers. Multiple, small, cutaneous nodules develop on the lower parts of the legs, usually about the fetlock. The nodules may follow lymphatics and extend to the proximal limb. The nodules are painless, develop a scab on the summit, discharge a small amount of pus and heal in 3–4 weeks. Succeeding crops of lesions may cause the disease to persist in the animal for months. Lymphangitis, causing cording of the lymphatics occurs.

Demonstration of Gram-positive spores in discharges is diagnostic, but difficult because of their low number in horses and cattle, as opposed to the high number of spores present in lesions in cats. The organism can be demonstrated in air dried smears of exudate stained with Wright's stain or Romanowsky stain.[1] The hyphal stage is rare in tissues. Injection of pus into rats or hamsters produces a local lesion containing large numbers of the yeast-like cells. The organism can be **cultured** on Sabourard's agar.

25.3.3.2.1.1

DIFFERENTIAL DIAGNOSIS

- Glanders
- Epizootic lymphangitis
- Ulcerative lymphangitis.

25.3.3.3

TREATMENT AND CONTROL

Systemic treatment with **iodides** (potassium iodide orally or sodium iodide intravenously) is the most effective treatment. Local application of tincture of iodine daily to ulcers may suffice in mild cases. **Itraconazole** might be effective.[1]

Prophylactic treatment of all cuts and abrasions, isolation and treatment of clinical cases, and disinfection of bedding, harness and gear will prevent spread of the disease in enzootic areas. Thorough washing of hands and arms with povidone iodine or chlorhexidine is recommended for humans handling infected animals or plant material.[1]

25.3.4

EQUINE PHYCOMYCOSIS (SWAMP CANCER, PITHYOSIS, HYPHOMYCOSIS DESTRUENS, FLORIDA HORSE LEECH, BURSATTEE)

25.3.4.1

Synopsis

25.3.4.1.1

Etiology

Pithyium insidiosum, *Basidiobolus haptosporus*, or *Conidiobolus coronatus*

25.3.4.1.2

Epidemiology

Tropical and subtropical areas of the world. Pythiosis occurs during the wet time of the year, but there is no seasonal distribution to *B. haptosporus* or *C. coronatus*

25.3.4.1.3

Clinical signs

All cause ulcerative granulomas. *P. insidiosum* causes lesions on the legs and ventral abdomen; *B. haptosporus* on the side of the body, neck and head; *C. coronatus* causes lesions in the oral, nasal, pharyngeal, and tracheal mucosae

25.3.4.1.4

Clinical pathology

Agar gel double diffusion test and histologic examination and immunohistochemical staining of tissue sections

25.3.4.1.5

Lesions

Ulcerative granulomas with sinus tracts containing yellow coagulated material

25.3.4.1.6

Diagnostic confirmation

Histologic examination of tissue

25.3.4.1.7

Treatment

Surgical excision. Sodium or potassium iodide. Vaccination

25.3.4.1.8

Control

None

25.3.4.2

ETIOLOGY

The causes are fungi including *Pythium insidiosum* (syn. *Hyphomyces destruens*), *Basidiobolus haptosporus* (syn. *B. haptosporus* var.*minor*), *Conidiobolus coronatus* (syn. *Entomophthora coronata*) and *Rhinosporidium* spp. *Pseudoallescheria boydii* causes granulomatous lesions of the nasal cavity.[1] *Alternaria alternata* causes small granulomatous lesions on the head of horses.[2] *Scedosporium prolificans* is associated with arthritis and osteomyelitis in horses.[3] Unidentified fungi also cause lesions containing black-colored granules or grains, the so-called “black-grain mycetomas”. *B. haptosporus* is a terrestrial fungus which lives in decaying vegetation.

25.3.4.3

EPIDEMIOLOGY

25.3.4.3.1

Occurrence

The disease occurs most commonly in **tropical and semitropical climates** but can occur in animals housed in temperate climates. Although the disease is recorded most commonly in horses it does occur in young cattle, dogs, and humans.[4,5]

Pythiosis occurs mostly during the monsoonal season, whereas infection by *B. haptosporus* and *C. coronatus* occur year round.[6] A survey in tropical northern Australia showed that granulomas of horses were caused by *Pythium insidiosum* in 77%, *B. haptosporus* in 18% and *C. coronatus* in 5% of cases.[6]

25.3.4.3.2

Animal risk factors

The fungi gain access to the subcutaneous tissues through wounds or other disruptions of the integrity of the skin or mucosa. A strong correlation between the occurrence of the lesions and frequent wetting and exposure to water is reported and is consistent with the concept of an aquatic life cycle and **motile zoospores** of *P. insidiosum*.[5] There is no breed, age or sex predilection.[6] Multiple cases can occur in horses maintained in the same enclosure.[7]

25.3.4.3.3

Zoonotic potential

Many of these fungi cause disease in humans, for instance, *Pseudoallescheria boydii* infection causes granulomas of the lower extremities of people in tropical regions and is referred to colloquiallyas Madura foot. However, there is no evidence of spread of infection from horses or other infected animals to humans, although appropriate caution should be exercised when handling infected tissues, especially by individual with compromised immune function.

25.3.4.4

PATHOGENESIS AND CLINICAL FINDINGS

The **life cycle** of *P. insidiosum* involves colonization of leaves of aquatic plants where the organism undergoes sexual reproduction and produces sporangia.[5] Motile zoospores, released from the sporangia, are attracted to plant and animal tissue, to which they adhere. Zoospores are attracted to damaged tissue on which they encyst and develop germ tubes. The hyphae invade tissue and produce the granulomatous reaction and ulceration. Ejected kunkers (necrotic material infected with hyphae) may produce sporangia.[5]

The large (20 cm), rapidly growing, circular, fibrotic, ulcerative granulomas caused by *Pythium insidiosum* usually develop on the lower limbs, ventral abdomen or thorax and contain yellow concretions in sinus tracts (leeches or kunkers). The lesions are pruritic and grow rapidly, often becoming >20 centimeters in diameter in one month *P. insidiosum*

lesions may involve underlying bone and **osteomyelitis** may be a common feature of chronic pithyosis of the lower limbs.[8] *Pithyium* sp. infection of the small intestine causes **eosinophilic enteritis** and granuloma formation resulting in colic and the need for surgical resection. Dissemination of infection from subcutaneous sites to liver, lung and spleen occurs and results in a progressive weight loss and eventual death.[9]

1480

1481

C. coronatus causes lesions similar, but smaller, to those of pithyosis. However, lesions are only on the nares, nasal passages, oral cavity, pharynx, or trachea.[10] The lesions can be very slow growing and take 1–2 years to become invasive, whereas others grow rapidly. *Pseudoallescheria boydii* causes granulomatous lesions of the nasal cavity in horses.[1] *B. haptosporus* causes ulcerative, granulating lesions that have a hemorrhagic, edematous surface, in contrast to the fibrotic lesions caused by *Pithyium* sp., on the sides of the **trunk, thorax, neck, and head**. Lesions caused by *B. haptosporus* are pruritic.

Alternaria alternata causes cutaneous nodules that are not painful or pruritic on the head of horses. The nodules may be solitary but are usually multiple and slowly progressive.[2]

Scedosporium prolificans causes infection of musculoskeletal structures including joints and bone, usually secondary to punct ure wounds or surgery.[3] This organism causes disseminated lesions and a fatal disease in immunosuppressed humans.

25.3.4.5

CLINICAL PATHOLOGY

Culture of the causative fungus is a laborious task but is necessary to demonstrate presence of the organism, although PCR detection is becoming available and could replace culture as the definitive diagnostic test. A PCR test has been developed for the identification of *Pythium* spp., this test also is useful for the detection of *C. coronatus*.[11] Horses infected with *Pithyium insidiosum* have a positive reaction to an **agar gel double diffusion test**, and complement fixation and intradermal hypersensitivity tests are also of diagnostic value.[12]

Examination of a biopsy specimen is also of value but care is needed to include a portion of necrotic tissue in which hyphae are most likely to be found. *Pseudoallescheria boydii* is indistinguishable from *Aspergillus* spp. on microscopic examination of tissue. **Immunohistochemical** staining methods, using indirect peroxidase techniques, are of value in distinguishing *Pythium* spp. from other fungi in swamp cancer lesions.[13]

Necropsy examination of horses with disseminated pythiosis reveals small, firm, irregularly branched, yellow-white masses in the regional lymph nodes draining cutaneous lesions and in liver, lungs and spleen. Histologically the masses are eosinophilic granulomas containing hyphal elements of *Pythium* spp.[9]

25.3.4.5.1

DIFFERENTIAL DIAGNOSIS

- Habronemiasis
- Granulation tissue
- Sarcoid
- Fibrosarcoma
- Amyloidosis of the nasal septum
- Squamous cell carcinoma
- Aspergillosis of the nasal septum
- Osteomyelitis.

25.3.4.6

TREATMENT

The most **efficacious treatment** for pythiosis and conidiobolomycosis is excision, although recurrence is common (30%) with larger lesions.[14] Laser ablation of the bed of the granuloma may reduce the rate of recurrence.[15] Larger lesions are usually treated medically. Fungal lesions respond to treatment of **sodium iodide** (20–40 mg/kg body weight, iv, q 24 h, as a 20% solution) followed by oral administration of **potassium iodide** (10–40 mg/kg po q 24 h for 7–120 days). Potassium iodide can also be administered at a dose of 10 g/425 kg once daily with the dose increasing by 2 g/day until the horse exhibits feed refusal or a dose of 20 g/day is achieved. Treatment should continue until signs of mycotic disease have resolved, which is often weeks to months. An alternative to potassium iodide is ethylene-diamine dihydroiodide (1.3 mg/kg, oral q 12 h for up to 4 months and q 24 h for up to one year).[1] Iodinism is a potential adverse effect of administration of sodium or potassium iodide although this is rarely observed.

Amphotericin also gives good results as a systemic treatment (intravenously 0.4 mg/kg body weight increasing to 1.5 mg/kg/day for 10–40 days) combined with local infiltration and after surgical excision in extensive lesions. Administration of amphotericin can be limited by its nephrotoxicity, which should be monitored during treatment. **Itraconazole** (3 mg/kg orally every 12 hours for 3–4 months) is effective in the treatment of *C. coronatus* infections of the nasal septum.[16] **Fluconazole** (14 mg/kg oral loading dose followed by 5 mg/kg q 12 h orally for 6 weeks) is effective in the treatment of nasal conidiobolomycosis in horses.[17] The pharmacokinetics of fluconazole in horses have been determined, permitting rationale dosing of this drug.[18] Ketoconazole is not effective for the treatment of *C. coronatus* in horses.

Miconazole (5 grams of 2% solution) infused for 4 weeks into lesions in the nasal cavity, in combination with systemic administration of iodides, was effective in treatment of nasal lesions caused by *Pseudoallescheria boydii*.[1]

Scedosporium prolificans is resistant to commonly used antifungal drugs.

A **vaccine** composed of elements of *Pithyium insidiosum* causes recovery or improvement in most cases.[19] It also causes a severe reaction, sometimes a cold abscess, at the injection site. Other complications include osteitis and laminitis which necessitate euthanasia.[19]

25.3.5

MADUROMYCOSIS

A skin disease of horses characterized by cutaneous granuloma caused by a variety of fungi including *Helminthosporium spiciferum*, *Brachycladium spiciferum*, *Curvularia geniculata* and *Monosporium apiospermum*. One or more lesions 1–2.5 cm in diameter appear anywhere on the skin but with a special frequency at the coronet. The incised lesion has a mottled appearance and drains pus containing the fungus.

25.3.6

MUCORMYCOSIS

A rare disease of humans, horses, cattle, and pigs caused by coenocytic fungi of the order Mucorales.[1] *Absidia corymbifera* causes severe disease and death of horses.[1] The disease is usually acute and progressive and antemortem diagnosis is difficult. Clinical signs include fever, diarrhea, circling, convulsions, and acute death.[1] Horses can have ulcerating skin lesions of the muzzle, nostrils, knees and hocks can develop in animals that survive the acute disease. Necropsy examination reveals demarcated necrotic or hemorrhagic lesions in the respiratory and gastrointestinal mucosa, lungs, spleen, and brain. Thin walled hyphae are visible in routine sections of tissue examined microscopically. There is no effective treatment or control.

26 Chapter 26 Diseases associated with protozoa

26.1 BABESIOSIS (TEXAS FEVER, REDWATER FEVER, CATTLE TICK FEVER, EQUINE PIROPLASMOSIS)

Babesia spp. are a diverse group of tick-borne, obligate, intra-erythrocytic Apicomplexan parasites infecting a wide variety of organisms. Infection of a vertebrate host is initiated by inoculation of sporozoite stage parasites into the bloodstream during the taking of a blood meal. Most babesial sporozoites directly invade circulating erythrocytes without a tissue stage of development. A few, notably, *Babesia equi* and *Babesia microti*, first invade lymphocytes where they form motile merozoites, which then invade erythrocytes, Once erythrocyte invasion occurs, a seemingly perpetual cycle of asexual reproduction is established, despite the rapid development of a strong immune response.

26.1.1 Synopsis

26.1.1.1 Etiology

Babesia spp.

26.1.1.2 Epidemiology

Disease of tropical and subtropical countries. Occurs in cattle, sheep and goats, horses, cervids, and pigs. Transmission by blood-sucking ticks. Young calves have innate resistance. Endemic stability occurs in herds with sufficient inoculation rate to immunize a high percentage of animals.

26.1.1.3 Zoonotic implications

Babesia bigemina and *B. microti* occurs in humans where tick is found. Human donor blood may be infected.

26.1.1.4 Clinical signs

Anemia, hemoglobinuria, jaundice, fever, high case fatality rate.

26.1.1.5 Clinical pathology

Parasites in stained blood smear, positive serology. PCR for detection of parasite in blood.

26.1.1.6 Necropsy lesions

Thin, watery blood, pallor, jaundice.

26.1.1.7 Diagnostic confirmation

Parasites in blood smear; vector present in environment.

26.1.1.8 Differential diagnosis list

A syndrome of acute hemolytic anemia should suggest the following alternative diagnoses:

26.1.1.9 Cattle

Theileriasis

Postparturient hemoglobinuria

Bacillary hemoglobinuria

S-methyl-L-cysteine-sulfoxide (SMCO) poisoning

Leptospirosis.

26.1.1.10 Horses

Equine infectious anemia

Paralytic myoglobinuria

Foals with alloimmune hemolytic anemia

Cardiac form of African horse sickness.

26.1.1.10.1 Treatment

Diminazene and imidocarb.

26.1.1.10.2 Control

Tick control, vaccination with live vaccine, chemoprophylaxis with imidocarb.

26.1.2 ETIOLOGY

The nomenclature of these intra-erythrocytic parasites is still subject to change; the current list is:

- **Cattle:** There are four species of bovine *Babesia* now recognized: *Babesia bovis* (includes *B. argentina*, *B. berbera*, *B. colchica*), *B. bigemina*, *B. divergens* (*B. cauxsica*, *B. occidentalis*, *B. karelica*) and *B. major*[1]
- **Sheep and goats:** *B. motasi*, *B. ovis*
- **Pigs:** *B. trautmanni*, *B. perroncitoi*
- **Horses:** *B. equi*, *B. caballi*. *B. equi* might be more accurately classified as a member of the Theileriidae family.

26.1.3 EPIDEMIOLOGY

26.1.3.1 Geographical occurrence

The distribution of the causative protozoa is governed by the geographical and seasonal distribution of the insect vectors that transmit them (Table 26.1)

26.1.3.2 Host occurrence

26.1.3.2.1 Bovine babesiosis

Bovine babesiosis associated with *B. bigemina* and *B. bovis* is an important disease of tropical and subtropical regions in the world, including the Americas. Both species are transmitted transovarially by *Boophilus* ticks, but only tick larvae transmit *B. bovis*, whereas nymphs and adults transmit *B. bigemina*.

In general terms, *B. bigemina* and *B. bovis* are infections which occur in countries in the tropics and subtropics **between 40°N and 32°S.** *B. major* and *B. divergens* occur in temperate regions.[1,2] Thus, *B. bigemina* occurs in South America, the West Indies, Australia, and Africa; *B. argentina* in the tropics including South and Central America, Australia, Asia, and southern Europe. *B. divergens* occurs in north-west Europe, Italy,[3] Spain, Eire, and is the principal cause of babesiosis in the United Kingdom. *B. bovis*

occurs in Europe, South America, and Africa; *B. berbera* in Mediterranean Europe and North Africa; *B. major* in the United Kingdom and Europe. The first report of *B. bovis* in Spain occurred in 2000.[4]

Babesia divergens bovine babesiosis transmitted by *Ixodes ricinus* is widespread and reported often in France.[5] The clinical incidence is low at 0.4% for the entire cattle population. The endemic situation is unstable and clinical cases occur more frequently with certain farming systems. Serology using immunofluorescence antibody test (IFAT), 7% of the cattle population is seropositive.[6] Using the PCR, prevalence rate of carriers is 20%.

Bovine babesiosis is widespread in South Africa, and the distribution of both *B. bovis* and *B. bigemina* is determined by the distribution of their vectors. The seroprevalence of *B. bigemina* in non-vaccinated cattle is due to the high vector tick population and the endemically stable situation which can be achieved by adopting a tick-control method which allows a reasonable number of ticks on cattle rather than relying entirely on intensive tick control and vaccination.[7]

26.1.3.2.2

Sheep and goats

In sheep and goats, babesiosis is associated with *B. ovis*, *B. motasi*, and occurs in southeastern Europe, North Africa, and South America.[8] In Iran, *B. ovis*, and *B. motasi*, occur in sheep and goats.[9,10] The prevalence of *B. ovis* and *B. motasi* in sheep and goats were 23.5%. 0.5%, and 14%, 0.5%, respectively. In Iran, the clinical signs of babesiosis occurred in 8% of infected sheep and 6.8% of infected goats. Splenectomized sheep can be used as a model for *B. divergens* chronic infection.[11]

1483
1484

Table 26.1 Major *Babesia* species infective to domestic animals, their tick vectors and geographical distribution[22]

Babesia spp.	Major ixodid vectors	Known distribution	Domestic species affected
Babesia bigemina	*Boophilus microplus* *Boophilus decoloratus* *Boophilus annulatus* *Boophilus geigyi* *Rhipicephalus everti*	Africa, Asia, Australia, Central and South America and Southern Europe	Cattle, buffalo
Babesia bovis	*Boophilus microplus*	As for *Babesia bigemina,* but less widespread in Africa due to *B. microplus* competition with *B. decoloratus*	Cattle, buffalo
Babesia divergens	*Ixodes ricinus* *Ixodes persulcatus*	North-west Europe, Spain, Great Britain, Ireland	Cattle
Babesia major	*Haemaphysalis punctata*	Europe, North West Africa, Asia	Cattle
Babesia ovata	*Haemaphysalis longicornis*	Eastern Asia	Cattle
Babesia ovis	*Rhipicephalus bursa*	South-eastern Europe, North Africa and Asia	Sheep and goat
Babesia motasi	*Rhipicephalus bursa*	South-eastern Europe, North Africa and Asia	Sheep and goat
Babesia caballi	*Dermacentor* spp. *Hyalomma marginatus* *Hyalomma truncatum* *Rhipicephalus evertsi evertsi*	Africa, South and central America and southern USD, Europe, Asia	Horses, donkey, mule
Babesia canis	*Rhipicephalus sanguineus* *Dermacentor* spp., *Haemaphysalis* spp. *Hyalomma* spp.	Southern Europe, North America, Asia, Africa, Australia	Dog

Babesia gibsoni	*Haemaphysalis* spp., *Rhipicephalus sanguineus*	Africa, Asia, Europe, North America.	Dog
Babesia trautmanni	*Rhipicephalus* spp.	Southern Europe, former USSR, Africa	Pig

Sheep babesiosis is of considerable economic importance in the areas infested with *Rhipicephalus bursa* which is widely distributed in the Palaearctic region between 31–45° parallels North including the Mediterranean basin,[8] the Balkans, the southern former USSR, Iraq, and Iran.

26.1.3.2.3

Porcine babesiosis

Associated with *B. trautmanni* and *B. perroncitoi*, porcine babesiosis occurs in southeastern Europe and Africa.

26.1.3.2.4

Equine babesiosis (piroplasmosis)

Babesiosis in the equine species is also known as **equine piroplasmosis**. In horses, donkeys, mules, and zebras the disease is associated with *B. equi* and *B. caballi*. It occurs in much of southern Europe, Asia, and the Americas. Equine piroplasmosis due to *B. equi* and *B. caballi* are widespread in China[12,13] and cause for serious concern in northeast China. Australia is free of equine piroplasmosis but did allow the temporary importation of seropositive horses into the country for the Sydney Olympic games of 2000.[14] While in Australia, seropositive horses were kept at certain restricted sites.

Seroepidemiologic studies of horse breeding farms in Brazil indicate the prevalence of *Babesia caballi* at 79%, *Babesia equi* 49% in mares; 36% of foals became infected with *B. equi* within 12 months but 100% with *B. caballi* within 10 months.[15] Maternal antibodies against *B. equi* and *B. caballi* in foals were 44 and 68%, respectively. Titers persisted for 1–5 months for *B. equi* and 1–4 months for *B. caballi*.

In South Africa, equine piroplasmosis is a tick borne disease of horses, mules, donkeys and zebras, associated with *Babesia caballi* and *Theileria equi*. Equine piroplasmosis is widespread in South Africa. A serological survey indicated that of all serum samples collected from all parts of the country, nearly 80% were positive for *T. equi*, and 50% were positive for *B. caballi* which was cultured from horses.[16]

26.1.3.2.5

Wildlife babesiosis

Babesia odocoilei infects the cervid family including the white-tailed deer (*Odocoileus virginianus*) and the American elk and American woodland caribou (*Rangifer tarandus caribou*).[17] Desert bighorn sheep (*Ovis canadiensis nelsoni*) and red deer (*Cervus elaphus elaphus*) are also susceptible to infection but do not exhibit clinical signs of disease.[17] *B. odocoilei* is transmitted by ticks, *Ixodes scapularis* and *Ixodes dammini*.

Fatal babesiosis in domestic reindeer associated with *Babesia tarandirangiferis* was first described in northern Russia in 1909. *B. divergens* has caused babesiosis in reindeer in Scotland.[18] Two morphologically dissimilar *Babesia* spp. have been cultured from reindeer in California.[19]

26.1.3.3

Origin of infection and transmission

Viable protozoa are present only in the bloodstream of animals in the active stages of the infection. Ticks are the natural vectors of babesiosis; the causative parasites persist and pass through part of their life cycle in the invertebrate host. Both *B. bovis* (Argentina) and *B. bigemina* pass part of their life cycle in the tick *Boophilus microplus* (recently reclassified as *Rhipicephalus* sp., but the name *Boophilus* will be used). *Boophilus* (*Margaropus*) *annulatus* and *B. microplus* are the major vectors of babesiosis, but other *Boophilus*, especially *B. decoloratus* in South Africa, *Rhipicephalus*, and *Haemaphysalis* spp. also act as vectors. *Boophilus microplus* is the main vector babesiosis associated with *B. bovis* and *B. bigemina* in cattle production systems in Central and South America.[20] *Ixodes ricinus* is the common carrier of *B. divergens* in the United Kingdom. *Rhipicephalus bursa*[8] and *Haemaphysalis punctata* spp. are the vectors in sheep; *Dermacentor*, *Rhipicephalus*, and *Hyalomma* spp. in horses; and *Rhipicephalus* and *Boophilus* spp. in pigs.

Information on the natural or experimental tick vectors of equine babesiosis is limited. *Dermacentor nitens* is the only tick species that transmits *B. caballi* in horses in the New World. In Brazil, *Ambylomma cajennense* and *Anocenter Dermacentor*) *nitens* are the most common and widespread ticks infesting horses, *A. nitens* is an important natural vector of *B. caballi*. *Boophilus microplus*, is the dominant tick in some areas where *B. equi* infection is endemic. Using conventional diagnostic methods, *B. microplus* collected from horses were negative for both *B. equi* and *B. caballi*. Using a nested PCR, *B. equi* and *B. caballi*

1484

1485

DNA were detected in the blood samples of horses and in the ticks. The detection of specific *B. equi* and *B. caballi* DNA in the eggs and larvae of *B. microplus* suggests the possibility of both transovarial and transstadial parasite transmission.[21]

In Iran, five ixodid species of ticks have been collected from sheep and goats.[9] The *Rhipicephalus sanguineus* and *Hyalomma marginatum* are the most common species in sheep and goats. Other tick vectors include *Dermacentor daghestanicus* in goats and *Hyalomma anatolicum*, *Hyalomma asiaticum* in sheep.[10]

When adult animals become infected they act as carriers for variable periods, up to 2 years. If they are constantly reinfected, as they are in an endemic environment, they act as carriers for life.

A knowledge of the life history of the tick is most important in applied control. Those ticks that parasitize only one host are easier to eradicate and cause less spread of the disease than those parasitizing two or three hosts. Control of ticks capable of surviving on both domestic and wild animals presents a major problem.

26.1.3.4

Life cycle and development of Babesia

The development of *B. bovis* and *B. bigemina* follow similar patterns in adult *Boophilus* spp. *Babesia* spp. do not parasitize any vertebrate host cell other than erythrocytes. Each sporozoite (merozoite) penetrates the cell membrane of an erythrocyte with the aid of a specialized apical complex. Once inside, it transforms into a trophozoite from which two merozoites develop by a process of merogony (binary fission) (see Fig. 26.1).

In the passage of host blood to the midgut of the tick vector, the development of two populations of ray bodies from the gamonts (gametocytes) occurs.[22] The ray bodies undergo further multiplication within the erythrocytes which continues after they have emerged. Large aggregations of multinucleated ray bodies form, but once division is complete, single-nucleated ray bodies that are now haploid and assumed to be gametes emerge from the aggregates and then fuse together in pairs (syngamy) to form a spherical cell (zygote). The zygote selectively infects the digestive cell of the tick gut where they multiply and then the basophilic cells where further multiplication occurs with development to kinetes that escape into the tick hemolymph. In the gut cells, schizogony occurs with the formation of polyploid kinetes (large merozoites). These motile club-shaped kinetes then escape into the hemolymph and infect a variety of cell types and tissues, including the oocytes where successive cycles of secondary schizogony occurs.

Thus, transovarial transmission occurs with further development occurring in the larval stage. Kinetes enter the salivary glands and are transformed into multinucleated stages (sporogony) and these then break up to form sporozoites. In all species, sporozoite development usually only begins when the infected tick attaches to the vertebrate host. In *B. bigemina*, some development occurs in the feeding larvae, but infective sporozoite take about 9 days to appear and therefore only occur in the nymphal and adult stages of the tick. Transmission can occur throughout the rest of the nymphal stage and by adult females and males. For *B. bovis*, the formation of infective sporozoites usually occurs within 2 to 3 days of larval tick attachment.

Contaminated needles and surgical instruments can transmit the infection physically. The ease with which infection can be transmitted in this way depends largely on the degree of parasitemia occurring with each species. Thus, the chances of physical transmission are slight with *B. bovis* and high with *B. equi* and *B. bigemina*.

26.1.3.5

Immunity and susceptibility to infection

The immune response of cattle to infection with *B. bovis* or *B. bigemina* involves both innate and acquired immune mechanisms[22] The immune response directed against infections with *Babesia* involves both humoral and cellular mechanisms and is T-cell dependent. In addition, an age-related immunity to initial infection with *B. bovis* in cattle is well established, characterized by strong innate immunity in young calves. Mononuclear phagocytes are engaged as the primary effector cells on innate and primary immune responses and nitric oxide has been identified as at least one babesiacidal molecule produced by activated mononuclear phagocytes. When *B. bovis* infected erythrocytes grown in culture are exposed to nitric oxide, death of the parasites occurs rapidly within the erythrocyte.

26.1.3.6

Innate immune mechanisms

There is an age-related immunity to primary infection of cattle with *B. bovis* and *B. bigemina*. Young calves possess this strong innate immunity against *B. bovis* infection that lasts for approximately 6 months after birth and is abrogated with the removal of the spleen.[23] Interleukin IL-12 and IL-10 are important immunoregulatory cytokines.[24] The protective innate response in young calves to infection with virulent *B. bovis* involves the early appearance of IL-12 and interferon-((IFN-() transcripts in the spleen. This is followed by a brief period of inducible nitric oxide synthase expression.[23] In contrast, IL-12 and

IFN-(mRNA) expression in the spleens of adult cattle which died from infection was delayed and depressed and occurred within the context of IL-10 expression. Also, in contrast to calves, there was no detectable antibody response before death in adults.

26.1.3.7

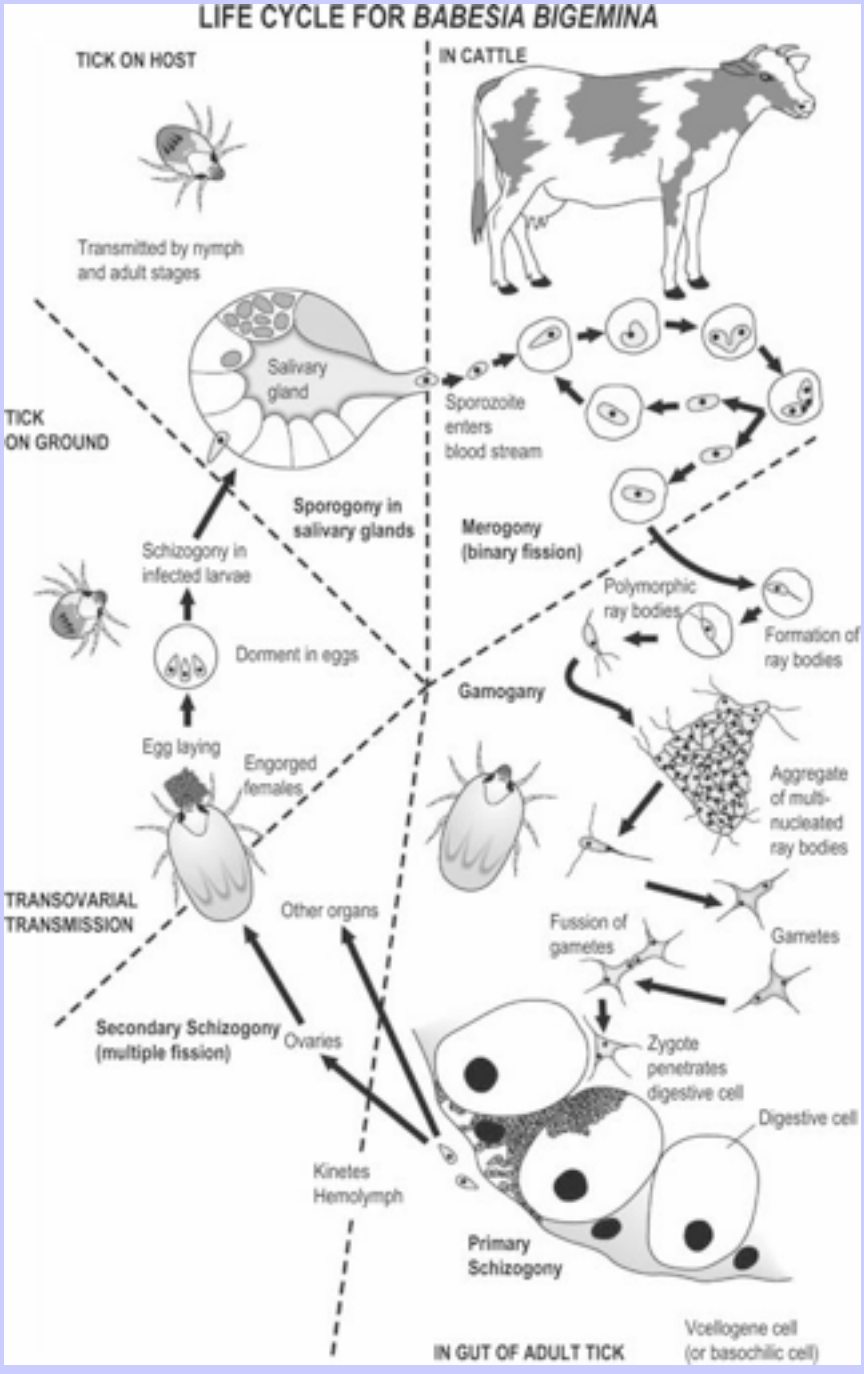
Acquired immune mechanisms

Following *B. bovis* infection, antibodies directed against protective and non-protective parasite antigens and host antigens are produced.[22] Hyperimmune serum from cattle infected with *B. bovis* many times, or a mixture of IgG1 and IgG2 prepared from hyperimmune serum of cattle can be used to immunize naïve calves passively against *B. bovis* infection, and the protection is strain specific. Splenectomized calves given hyperimmune serum and challenged with *B. bovis* recover as effectively as intact calves.

Strong immunity occurs after natural infection with most *Babesia* spp. There appears to be little relationship between the degree of immunity and the level of antibodies in the serum. If the infection recurs repeatedly the immunity is permanent. If the illness is treated urgently and efficiently, and the protozoa are killed before antibodies are produced, no immunity occurs. If the infection is not repeated the protozoa survive in the host for a variable time, usually about 6 months, and then disappear. A sterile immunity persists for a further 6 months and the host is susceptible again about a year after infection occurred. These periods of latent infection and resistance to reinfection are subject to significant variation and to different responses between breeds of cattle and the species of *Babesia*.

Despite the potential severity of the acute infection, individuals who survive generally develop immunity against disease, but not against infection, and could remain persistently infected. In the case of *B. bovis*, infections can persist for years, and even for the lifetime of the animal. Babesial infections have adapted well to survival in immune hosts. At least five different phenomena are known to contribute to parasite survival: rapid antigenic variation; cytoadhesion and sequestration; binding of host proteins to the infected red blood surfaces; the monoallelic expression of different members of multigene families; and establishment of transient immunosuppression.[25]

Fig. 26.1 The development life cycle of *Babesia bigemina* in cattle and the ixodid tick vector *Boophilus microplus* (adapted from Mehlhorn, Shein 1984; Mackenstedt et al. 1995; Gough et al. 1998).



The inoculation rate measures the daily probability of infection. This is based on the knowledge that animals exposed to the parasite in the first 9 months of life become infected, immune and seropositive without showing any clinical signs of disease.[20] Inoculation rates of 0.0005 and 0.005 are endemically unstable because a high percentage will reach the age of 9 months without having been exposed to the hemoparasite. This results in a high risk of disease (**endemic instability**), as primary infections in older animals are usually severe and can be fatal. A serological survey of cattle in Bolivia for *B. bovis* and *B. bigemina* to estimate the risk of outbreaks by calculating the inoculation rates of each hemoparasite. The results indicated the area surveyed is endemically unstable as *h* values were below 0.005.[20] In such unstable conditions, calfhood vaccination against hemoparasites is recommended to ensure that the herd is immune. Alternatively, cattle producers may use tick control to break the transmission cycle; however, tick control is much more costly and risky if tick control fails.

Endemic stability is defined as the state where the relationship between host, agent, vector and environment is such that clinical disease occurs rarely or not at all.[22] Endemic stability (herd immunity) in bovine babesiosis occurs when the rate of transmission (inoculation rate) of *Babesia* spp. by the tick vector is sufficient to immunize a majority of susceptible calves before the loss of calfhood resistance.[26] In tropical areas with a high vector population, natural exposure usually occurs at an early age and cattle are therefore immune to subsequent challenges as adults. If at least 75% of calves are exposed to *B. bovis* infection by 6 to 9 months of age the disease incidence will be very low and a state of natural endemic stability would exist.

26.1.3.7.1

B. bovis and B. bigeminacross

protection. Protective cross species immunity against infection cannot be induced with *B. bovis* and *B. bigemina*.[22]

26.1.3.7.2

Duration of immunity

Cattle develop a durable long-lasting immunity after a single infection with *B. divergens*, *B. bovis*, or *B. bigemina*. Immunity to both *B. bovis* and *B. bigemina* lasts at least 4 years. There is evidence in the literature suggesting the presence of antibodies is not necessarily an indication of immunity nor is absence of detectable antibodies necessarily an indication of a lack of immunity.[22]

26.1.3.8 Risk factors

26.1.3.8.1 Host factors

Bos indicus breeds of cattle are much more resistant to babesiosis than ***Bos taurus*** breeds. This phenomenon is thought to be a result of the evolutionary relationship between *Bos indicus* cattle, *Boophilus* spp. and *Babesia*.[22] Zebu and Afrikaner cattle have a higher resistance to *B. bovis* than British and European breeds; Santa Gertrudis and cross-bred cattle occupy an intermediate position. Zebu-type cattle also enjoy a relative freedom from the disease because of their resistance to heavy infestations with ticks.

In Australia, *B. bigemina* is usually of lower pathogenicity than *B. bovis* and rarely lethal even when fully susceptible adult cattle are introduced to an endemic area.[27] Inoculation studies with *B. bigemina* in Australia have shown that *B. indicus* and *B. indicus* cross cattle are more resistant than the *B. taurus* cattle.[27]

Age resistance There is a variation in susceptibility to infection according to **age** in cattle. The severity of clinical babesiosis increases with age. Calves and foals from naïve dams are highly susceptible to infection and clinical illness from birth to 2 months of age, at which time they develop an innate resistance that persists to about 6 months of age. Calves and foals from immune dams receive antibodies via the colostrum, and this passive immunity persists for 3–4 months after birth. The greatest infection rate is in animals in the 6 to 12-month age group; infection is uncommon in animals over 5 years of age. Animals under 1 year of age are infected predominantly with *B. bigemina* and those over 2 years of age by *B. bovis*. Calves up to 1 year of age, although fully susceptible to infection, are resistant to disease.[2] The average age at which calves in endemic areas become infected is 11 weeks (2–34 weeks), but at this early age clinical signs and pathological changes are mild and short-lived. After 6 months of age the number of infected animals in enzootic areas increases.

1486 1487

In housed cattle, the level of antibodies in the patient are at their lowest when the cattle come out of the barn in the spring, and gradually increase as they are exposed to vector ticks.

In **enzootic areas**, the animals most commonly affected by clinical disease are susceptible cattle introduced for breeding purposes, for slaughter, or in transit. Cattle

indigenous to these areas are rarely affected because the natural resistance of the very young, and passive immunity via colostrum from immune dams is gradually replaced by a state of active immunity. Severe clinical cases occurring in these cattle are usually caused by exposure to some stress, such as parturition, starvation or intercurrent disease. Such breakdowns in immunity are most likely to occur if there is a superimposed infection with a different parasite, especially *Anaplasma marginale*.

26.1.3.8.2

Environmental factors

There is a **seasonal variation** in the prevalence of clinical babesiosis, the greatest incidence occurring soon after the peak of the tick population. For example, in England babesiosis is largely a disease of spring, summer, and autumn for this reason. Of the climatic factors, air temperature is the most important because of its effect on tick activity – higher temperatures increase it; humidity and rainfall have little effect – and even with temperature the effect is limited once a threshold of 7–100°C (44–50°F) minimum temperature is exceeded. Heaviest losses occur in **marginal areas** where the tick population is highly variable depending on the environmental conditions. In seasons when the tick population decreases, infection may die out and immunity be lost. Then in favorable seasons when ticks multiply, the infection spreads quickly amongst what has become a susceptible population. Comparable circumstances may be created artificially by an inefficient dipping program, which reduces the tick population to a low level and is subsequently unable to keep it under control.

26.1.3.8.3

Pathogen factors

Many intra-erythrocytic hemoparasites survive the host immune system through rapid antigenic variation which has been demonstrated for *Babesia bovis* and *Babesia rodhaini*.[28] The molecular basis for antigenic variation in babesial parasites and its possible connection with cytoadherence and sequestration have been examined.[28] The existence of different strains and antigenic variation occur in both *B. bovis* and *B. bigemina*. Babesial infections in cattle by antigenic variation and by superinfection with antigenically different parasite populations. Each change in antigenic type provides a temporary respite from attack by the host immune system and prolongs the infection period. The number of antigenically distinct relapses which can occur in a herd with babesial infection could be more than 100.

Strain differences and antigen variation do not appear to be of major importance as a cause of disease or in vaccines, since cross-immunity tests between strains usually provide adequate clinical protection against each other. *Babesia bigemina* sporozoites expressing specific antigens which induce protective immunologic responses in cattle have been characterized.[29]

New sequences of Spanish isolates of *B. caballi* and *B. equi* show a relatively high degree of genetic divergence within the group of piroplasms.[30] The immunoreactive polypeptides of *B. equi* merozoite antigen have been identified.[31]

26.1.3.9

Economic importance

Bovine babesiosis is the most economically important of these diseases, because of direct losses of production and because of restriction of movement of cattle for trade by quarantine laws. Many animals die or undergo a long period of convalescence entailing loss of meat and milk production. Incidental costs of immunization and treatment add to the economic burden. With early, effective treatment the mortality rate can be reduced to 5%.

The mortality rates in outbreaks of equine babesiosis are high, but the big losses in this species result from the interference with racing and pleasure horse meetings and competitions. This is especially the case at present with the movement of horses between countries to compete in increasingly international equine competitions. An additional form of loss is the death of foals infected in utero. In the 1960s with an outbreak of clinical equine babesiosis in the United States, several cases in Australia, and several seropositive identifications in the United Kingdom, it appeared to be an emerging disease which threatened to be of major importance to the horse industry, but this has not eventuated.

The morbidity and mortality rates and the losses associated with babesiosis in other animal species are difficult to determine because they exist as enzootic diseases in areas where they occur.

26.1.3.10

Zoonotic implications

Human cases of *B. divergens* infection have been reported in France, Britain, Ireland, Spain, Sweden, Switzerland, the former Yugoslavia, and the former USSR.[2] Geographically, they coincide with *B. divergens*-infected cattle populations and *Ixodes*

ricinus-infested areas, involving inhabitants of rural areas who are exposed to ticks by virtue of their occupation or their recreational activities. Most cases are reported between May and October, during main season of tick activity. *B. divergens* is the primary cause of human babesiosis in Europe, resulting in fatality rates of 42% among persons who have been splenectomized and 5% among those with intact spleens. *B. divergens* has caused human babesiosis in North America in a splenectomized person which suggests that *B. divergens* may be emerging in North America in areas where such infections are not endemic.[32] The known vector tick, *I. ricinus* is not indigenous to North America.

There is evidence that human babesiosis in the US has been associated with *B. microti*, a parasite of white-footed mice, is transmitted by deer ticks.[33] Deer-associated zoonoses have become a major public health concern in the United States because human contact with deer ticks has increased as a result of the proliferation of deer, abandonment of farmland that reverts to thick secondary vegetation, and increased use of coastal sites for human recreation. This explains the increasing frequency of reported human cases of Lyme disease, babesiosis and human granulocytic ehrlichiosis.[32]

Babesia represent a potential threat to the blood supply for transfusion since asymptomatic infections in humans are not uncommon and spread of the parasite via blood transfusions has been reported from various countries.[34] Using the microaerophilous stationary phase (MASP) culture technique, the parasites proliferate in a settled layer of blood cells. This provides the opportunity to examine the basic biology of the organism, as well as the host-microbe interactions, immune factors triggered by the parasite, factors involved in innate resistance of young animals to infection, and antimicrobial susceptibility. Their in vitro cultivation can produce quantities of parasite nucleic acid needed for defining phylogenetic relationships of these species, developing methods for detection of the parasite in otherwise asymptomatic individuals, and producing parasite antigens and attenuated strains of *Babesia* that could be used for immunization.

1487 1488

26.1.4 PATHOGENESIS

Babesia spp. are a diverse group of tick-borne, obligate, intra-erythrocytic Apicomplexan parasites infecting a wide variety of organisms. Infection of a vertebrate host is initiated by inoculation of sporozoite stage parasites into the bloodstream during the taking of a blood meal. Most babesia sporozoites directly invade circulating erythrocytes without a tissue stage of development. Once erythrocyte invasion occurs, a perpetual cycle of asexual reproduction is established despite the rapid development of a strong immune response.[25]

26.1.4.1

Acute cases

When an animal becomes infected, multiplication of the protozoa in the peripheral vessels (*B. bigemina*, *B. ovis*), or in the visceral vessels (*B. bovis*), reaches a peak with the development of clinically detectable hemolysis, the principal pathogenic effect, after an incubation period of 7–20 days. The hemolysis results in profound anemia, jaundice, and hemoglobinuria. A fatal outcome due to anemic anoxia commonly follows. In longer surviving animals there are ischemic changes in skeletal and heart muscle.

In *B. bovis* infections there is also a profound vasodilation and hypotension, resulting from stimulation of production of vasoactive substances, and an associated increase in vascular permeability. Circulatory stasis and shock follow; disseminated intravascular coagulation (DIC) and subsequent, fatal pulmonary thrombosis are also features. Cerebral babesiosis is possible.

B. bigemina is an uncomplicated hemolytic agent and does not exert these vascular and coagulation effects.

Susceptibility to infection with *Babesia* spp. decreases with age, but the severity of the clinical disease increases. For example, calves up to 5–6 months of age, and infected with *B. bovis*, show little effect; cattle of 1–2 years of age have a moderately severe disease; and aged cows suffer a severe, often fatal, clinical disease. Intrauterine infection of 2-day-old calf with *Babesia bovis* has been reported.[35]

B. odocoilei infection in elk causes an acute hemolytic anemia which may be fatal.[17]

Animals which survive become **carriers**, a state in which a harmless, subclinical infection is maintained by a delicate immunological balance between protozoa and antibodies. This balance is readily disturbed by the stress of transport, deprivation of food, pregnancy, or intercurrent disease. Carrier animals are resistant to infection with *B. bovis* for up to 2 years. With **constant reinfection**, such as occurs in an enzootic situation, the protection is continuous, but the virulence of the blood in transmission experiments varies due to periodic disappearance of infective forms of the parasite from the peripheral blood.

The ability of cattle to infect ticks is much longer (1 year) with *B. bovis* than *B. bigemina* (4–7 weeks). Similarly, the peak incidence is at a younger age and the reinfection rate is faster with *B. bigemina*.

In **pregnant cows** there is no apparent infection of the calf in utero, but passive immunity is transferred via colostrum to the newborn calf.

26.1.4.2

Immunology

Calves less than 9 to 12 months of age are as susceptible as adult cattle to infection with *B. divergens* but are less likely to exhibit clinical disease. This phenomenon known as inverse age resistance is due to innate resistance in calves and is independent of the maternal immune status. Although offspring of resistant dams acquire specific antibodies (mainly IgG) via colostrum, these immunoglobulins are not necessary for protection because calves of susceptible dams without specific antibodies are equally resistant. In vitro studies with *B. bovis* show that erythrocytes of very young calves were unfavorable to parasitic development, possibly because of the inhibitory effect of fetal hemoglobin.[2]

Cattle that recover, either naturally or after chemotherapy, from acute infection with *B. bigemina* or *B. bovis* remain persistently infected and resistant to further disease upon reinfection with the same strain.[36] Immunization with killed parasites or parasite extracts can afford protection against homologous and heterologous strain challenge, indicated by low parasitemias and diminished reduction in packed cell volume.

Immunity does not last indefinitely, and in the absence of exposure to further infection, the animal becomes susceptible to reinfection. Specific immune mechanisms include both cellular and humoral components. Monocytes and lymphocytes are the main agents of cell-mediated immunity. Experimentally, the exposure of cattle to avirulent and virulent strains of *B. bovis* causing a primary infection, results in considerable antimicrobial activity in peripheral blood monocytes and neutrophils.[37] The elevated antimicrobial activity is coincident with the time that parasite numbers peaked in the circulation and occurs prior to parasite clearance. This suggests that peripheral blood monocytes and neutrophils are active mediators in the innate immune response to a primary infection with *B. bovis*. In cattle vaccinated against *B. divergens*, protection is correlated with elevated mononuclear cell proliferation.

In cattle infected with *B. divergens*, antibodies can be demonstrated even before infected erythrocytes appear in blood smears, indicating that they have no inhibitory effect on parasite multiplications. During secondary infections, protection seems to depend on the high specificity of some antibodies rather than the total level of anti-*B. divergens* antibodies, as resistant animals frequently have very low levels of specific antibodies.

The importance of the spleen in the specific immune response is illustrated by the fact that removal of the spleen following recovery may result in clinical relapse.

Specific antibodies to the parasites are produced and are used in serological diagnosis. The highest titers are obtained in the sera of cows that have had a series of infections and reinfections, but the degree of immunity resulting is not related to the antibody titer. The antibodies can be passively transferred via serum or colostrum. The immunity to each strain of *B. bovis* is specific. However, when an infection with a heterologous strain of the protozoa occurs, there is an increased immune response.

Experimental transmission of *B. ovis* infection in sheep produces an acute attack of clinical illness, parasitemia, and the subsequent development of immunity, as in cattle. Experimental infection of pregnant cattle with *B. bigemina* results in an immune response similar to nonpregnant animals.[38]

26.1.5 CLINICAL FINDINGS

26.1.5.1 Cattle

26.1.5.1.1 Babesia bovis.

The acute disease generally runs a course of 3 to 7 days and a fever of >40°C is usually present for several days before other signs become obvious.[22] This is followed by inappetence, depression, polypnea, weakness and a reluctance to move. Hemoglobinuria is often present (known as redwater in some countries); urine is dark-red to brown in color and produces a very stable froth. Anemia and jaundice develop especially in more prolonged and severe cases. Diarrhea may occur. Muscle wasting, tremors and recumbency develop in advanced cases followed terminally by coma. Many severely affected animals die precipitately at this point, after an illness of only 24 hours. Metabolic acidosis is present in a significant percentage of cases of bovine babesiosis in Ireland.[39] During the fever stage, pregnant cattle may abort and bulls may become sterile for 6 to 8 weeks. Cerebral babesiosis is manifested by incoordination followed by posterior paralysis, or by mania, convulsions and coma. The mortality rate in these cases is high in spite of treatment.

In those that survive, the febrile stage usually lasts for about a week and the total course about 3 weeks. Animals that survive recover gradually from the severe **emaciation** and anemia, which are inevitable sequelae.

A **subacute** syndrome also occurs, especially in young animals, in which the fever is mild and hemoglobinuria is absent. The syndrome in infection with *B. divergens* is similar to the above, except that in addition, there is spasm of the anal sphincter causing the passage of feces with great force in a long, thin stream, even in the absence of diarrhea. The sign is referred to as **'pipe-stem'** feces.

26.1.5.1.2

Babesia bigemina.

Hemoglobinuria is present earlier and more consistently than in *B. bovis* infections and the fever is less of a feature. Acutely affected animals are usually not as severely affected as those with *B. bovis* infections. There is no cerebral involvement and recovery in non-fatal cases is usually rapid and complete. However, in some cases the disease can develop very rapidly with sudden and severe anemia, jaundice and death.[22] Animals which recover from *B. bigemina* remain infective for ticks for 4 to 7 weeks and carriers for only a few months.

26.1.5.2

Sheep

Anemia, fever, icterus and hemoglobinuria are common.[8]

26.1.5.3

Horses

The incubation period is 8–10 days. **Acute** cases in adults show a sudden onset of immobility and reluctance to move; some are in lateral recumbency and do not respond to stimuli. There is complete anorexia and fever of 40°C (104°F), although the fever often subsides after 1 day and becomes intermittent. Edema of the fetlocks occurs and may also be present on the head and ventral abdomen. Fecal balls are covered with thick mucus, and colic occurs frequently. Often there is no hemoglobinuria; bronchitis occurs occasionally. The mucosae are pale pink and tinged with jaundice. In **young horses**, the signs are more severe – jaundice, mucosal pallor and weakness are marked, and mucosal petechiae are evident. The course is 8–10 days. Afflicted horses may die within 24–48 hours of the first signs appearing. **Chronic** cases may survive for months and 'carriers' may persist for as long as 4 years. The experimental disease produced by *B. equi* is mild. A high percentage

of erythrocytes are parasitized by the protozoa and the horses are anemic, but there is no clinical evidence of anemia. Newborn **foals** develop severe jaundice and severe prostration, sometimes delayed in onset by 2 or 3 days after birth.

26.1.5.4 Wildlife

Babesiosis in elk and caribou are characterized clinically by lethargy, hemoglobinuria, icterus, fever, recumbency, and sudden death.[17] Elk infected with *B. odocoilei* may not have any clinical signs of disease, but may become ill during periods of stress, such as the rutting season, calving, transportation, or overcrowding.

26.1.5.5 Other species

In all other species the syndrome observed is clinically similar to that described for cattle.

26.1.6 CLINICAL PATHOLOGY

26.1.6.1 Clinical cases

26.1.6.1.1 Hematology

Severe anemia with erythrocyte counts as low as 2 million/μL and hemoglobin levels down to 3 g/dL occur in clinical cases in cattle and horses, the anemia peaking 9–16 days after infection occurs. Significant falls in platelet counts and a depression in the fibrinogen content of the blood also occur.

26.1.6.1.2 Demonstration of Babesia

26.1.6.1.2.1 Direct examination of blood smears.

A diagnosis of existing babesiosis in clinically affected animals of all species depends on the demonstration of protozoa in a Giemsa-stained smear of capillary blood; venous blood may give a false-negative in *B. bovis* infections. There is no exact correlation between the percentage of erythrocytes containing protozoa and the severity of the clinical signs. Also in *B. bigemina* infections, protozoa are numerous in peripheral capillaries; *B. bovis* is much less readily found. This difficulty can be largely overcome by the use of thick blood smears. Microscopic examination can detect parasitemia of about 10^5 in thin blood films and 10^6 in thick blood films.

For best results, blood films should be prepared from capillary blood collected after pricking the tip of the tail or margin of the ear. Blood from the general circulation may contain 20 times fewer *B bovis* than capillary blood. Thick blood films are 10 times more sensitive and are more reliable for the detection of low level *B. bovis* infection.[22]

26.1.6.1.2.2

Transmission test.

Subinoculation of blood to susceptible splenectomized calves is highly sensitive technique for direct detection of *Babesia* infection. In **transmission tests**, 50–100 mL of blood are injected into the recipient either SC or IV. In the latter case, the incubation period will be shorter. The recipients are examined daily and the blood examined for protozoa at the peak of the febrile reaction.

Carrier cattle infected with *B. bovis* and *B. bigemina* are difficult to detect because of the small number of parasites in peripheral blood. Microscopic examination of blood films is not reliable technique for detection of *Babesia*-carrier animals. The evaluation of persistence of *B. bovis* and *B. bigemina* infections require subinoculation of blood into splenectomized calves, and measurement of the anti-babesial antibody level.[40]

26.1.6.1.2.3

Culture of *Babesia*.

Babesia divergens from the blood of **carrier cattle** can be isolated using an in vitro culture technique in sheep erythrocytes.[41] The protozoa could be isolated 9 months after the acute babesiosis phase, and can be successfully subcultured, cryopreserved and resuscitated using culture medium. This will allow for more detailed examination of the organism.

Preservation of live protozoa can be effected by cryopreservation, by culture in a medium containing infected bovine erythrocytes, and in simple culture media in special machinery for long periods and in large quantities.

26.1.6.2

PCR detection and identification of Babesia spp.

A universal PCR assay for the detection and identification of nine of the most common pathogenic bovine, equine, and rodent piroplasms, including *B. divergens*. Following specific amplification of the parasite DNA by nested PCR, the parasite species is identified

by PCR-restriction fragment length polymorphism.[2] Various applications of the PCR have detected *B. bovis* and *B. bigemina* parasitemias at levels of 10^{-7} to 10^{-9}.

The most recently introduced tests are an ELISA using a recombinant *B. bovis* antigen, PCR and a DNA probe, which can detect specific parasitemias at very low levels of infection. The DNA probe has the added advantage of being able to detect protozoa in necropsy specimens and in tick tissues. The PCRs are most useful because of their high sensitivity, which makes them ideal for the detection of carrier animals.

A PCR assay can detect *B. equi* and *B. caballi* from the blood of horses which have recovered from the acute phase of babesiosis. The may assume a subclinical, chronic course and the animals are carriers and may act as reservoirs of infection, and parasites are present in very low numbers in the blood and generally not detectable in Giemsa-stained blood-smears.[42] In these horses the complement fixation test which is the official test for the diagnosis of babesiosis in horses may be negative and the PCR test is positive. A nested PCR assay has been used to detect natural infection of *Boophilus microplus* and the blood of horses with *B. equi* and *B. caballi* in Brazil.[21] The nested PCR is considered superior to both Wright–Giemsa-stained and primary PCR methods for the routine detection of *B. equi* in horses.[43]

1489

1490

26.1.6.3

Serology

Diagnosis of **past or present infection** is adequately demonstrated by any one of a wide range of serological tests.

26.1.6.3.1

Bovine

Because of the difficulty in finding protozoa in smears in animals during the subclinical stages of the disease, especially in surveillance studies for the detection of the infection in herds or areas, much attention has been directed to serological tests. These are now well-established, but none of them enjoys a completely satisfactory reputation.

26.1.6.3.1.1

Complement fixation test (CFT).

The CFT has been the most used serological test for bovine babesiosis. Other tests being assessed in field conditions include a passive agglutination test, an indirect fluorescent antibody test (IFAT), an indirect hemagglutination test, an ELISA, a microplate enzyme immunoassay (EIA), a latex agglutination test, a capillary

agglutination, a slide agglutination, and a card agglutination test. All of the tests have good reputations, with the EIA being probably the most sensitive.

26.1.6.3.1.2

Immunofluorescence antibody test (IFAT).

The IFAT has been a popular test used to distinguish between *Babesia* spp. and to demonstrate the presence of antibodies in a population. IFAT clearly differentiates between antibodies to *B. divergens* and other bovine babesias but not between *B. divergens* and *B. capreoli* from red deer.

26.1.6.3.1.3

ELISA.

An ELISA system using a crude antigenic preparation of *B. bovis* has been standardized for the detection of IgM antibodies with a specificity of 94% and sensitivity of 100%.[44] Specific IgM antibodies against *B. bovis* first appeared on the 11th day post-inoculation in animals infested with *B. microplus* ticks and on the 19th day post-inoculation in which animals had been inoculated with infected blood.

A competitive ELISA (cELISA) is an accurate, reliable, easily standardized, and high-throughput method for detecting hemoparasite infections.[45] The gene encoding *B. bovis* rhoptry-associated protein 1 (RAP-1) was used to develop the assay.[46] The cELISA accurately differentiated animals with *B. bovis*-specific antibodies from uninfected animals and from animals with antibodies against other tick-borne hemoparasites (sensitivity 98.5%, 98.7% specificity).

26.1.6.3.2

Sheep

An ELISA is available for the detection of *B. ovis* in sheep.

26.1.6.3.3

Equine

In the horse, the tests used include the widely used complement fixation test, and the recently introduced, still undergoing testing, ELISAs and DNA probes. Important aspects of serological testing in horses is its application in the implementation of **import and export** regulations, in deciding the action to be taken in releasing very valuable horses from quarantine, and in deciding whether or not to permit entry of individual horses into non-enzootic areas.

A **latex agglutination test (LAT)** using recombinant *B. equi* merozoite antigen 1 (EMA-1) has been developed for the detection of antibodies to *B. equi*.[47] It is a simple, rapid, sensitive, specific and inexpensive alternative to IFAT or ELISA.

Because of the importance of testing individual horses, in the process of babesiosis control the **culture of blood** from suspect horses is now used to determine whether or not they are carriers of *B. equi*.

26.1.7

NECROPSY FINDINGS

In **acute cases** of babesiosis in all species, in which patients die after a brief illness and during an anemic crisis, the typical lesions are jaundice, thin watery blood, pale tissues, enlargement of the spleen which has a soft, pulpy consistency, and gross enlargement and dark brown discoloration of the liver. The gallbladder is distended with thick, granular bile, the kidneys are enlarged and dark, and the bladder contains red-brown urine. Ecchymotic hemorrhages are present under the epicardium and endocardium, and the pericardial sac contains an increased quantity of blood-stained fluid. A characteristic lesion in both cattle and horses is severe intravascular clotting.

In **subacute or chronic cases** of fairly long duration, the carcass is emaciated but hemoglobinuria is absent; the other changes observed in acute cases are present but less pronounced. **Laboratory examination** of smears taken from peripheral blood, from kidney and heart muscle and, in the case of suspected *B. bovis* infection, from the brain, is mandatory for clinching the diagnosis. The smears from blood and most tissues must be made within 8 hours of death, in the case of brain within 28 hours, and stained with Giemsa for the detection of *B. bovis*.

Direct fluorescent antibody staining of smears permits the use of slightly older tissues. Organ smears are still usable 5 days after collection provided they are kept stored at 22°C (72°F). With *B. bigemina* the morphology of the parasite changes quickly after the host's death so that they resemble *B. bovis*. Blood serum collected after death can also be used for detection of antibodies in serological tests.

26.1.7.1

DIFFERENTIAL DIAGNOSIS

For diagnostic confirmation the presence of the insect vector must be verified before the diagnosis of babesiosis can be made, unless the animal has left an enzootic area within the preceding month. Clinically, a high morbidity and case fatality rate in cases showing

jaundice with hemoglobinuria and fever are suggestive, but confirmation of the diagnosis by examination of blood smears or by transmission experiments is essential. A necropsy showing splenomegaly, jaundice, hemoglobinuria, swollen dark kidneys and liver, and myocardial ecchymoses, while highly suggestive, should also be confirmed by laboratory examination of tissues for the presence of the causative protozoa.

26.1.7.1.1

Differential diagnosis list

A syndrome of acute hemolytic anemia should suggest the following alternative diagnoses:

Cattle (see Table 26.2):

- Theileriasis (*Theileria annulata*) – very similar clinically and differentiable only on laboratory examination
- Postparturient hemoglobinuria – does not require the presence of vectors, occurs only in recently calved cows in full milk and on low phosphorus diets, and is characterized by the absence of protozoa from blood and tissues
- Bacterial hemoglobinuria – characterized by a necrotic infarct under the diaphragmatic surface of the liver in cattle grazing lush pasture
- S-methyl-L-cysteine-sulfoxide (SMCO) poisoning – occurs only in cattle grazing crops of rape or other *Brassica* spp.
- Leptospirosis – occurs only in this form of the disease in calves kept in unsanitary conditions which are wet underfoot. Diagnosis of this disease depends on isolation of the leptospires.

Horses (see Table 26.3)

- Equine infectious anemia – has a much longer, recurrent course, occurs in sporadic cases only and is not associated with protozoa in body fluids and tissues

- Paralytic myoglobinuria – red urine is due to myoglobinuria, always associated with recent vigorous exercise and elevation of serum creatine phosphokinase levels
- Foals with alloimmune hemolytic anemia – detectable only on laboratory examination for evidence of incompatibility between the serum of the dam and the foal's erythrocytes
- Cardiac form of African Horse Sickness – edematous lesions occur similar to those in babesiosis, but in which there is no hemoglobinuria or jaundice.

1490

Table 26.2 Differential diagnosis of diseases of cattle in which red urine is a principal manifestation

		Clinical and laboratory findings		
Disease	**Epidemiology**	**General**	**Urinary**	**Clinical pathology**
Diseases with hematuria				
Enzootic hematuria	Subjects older than 1 year. Endemic to specific areas with access to bracken.	Persistent intermittent hematuria, hemorrhagic anemia, acute or chronic. Rectal in acute cases nil; chronic cases have local or diffuse thickening. Long course, death by anemia.	Persistent, intermittent hematuria.	Urine has no pus, eukocytes or bacteria.
Enzootic bovine pyelonephritis	Adults only. Sporadic cases usually. May be a series suggesting origin in one bull and relationship to mating events.	Mild fever. Frequent painful urination, toxemia. Late cases, rectal examination shows cystitis, ureters thickened and enlarged, kidneys the same. Pain on palpation. Long course, death by uremia.	Intermittent hematuria and pyuria.	Urine has pus, erythrocytes, eukocytes, *Cor. renale* on culture catheter sample.
Diseases with hemoglobinuria				
Babesiosis (*B. bigemina* and *B. bovis*)	Outbreaks in marginal areas in heavy tick seasons in calves. Incubation 2–3 weeks. 90% morbidity and mortality.	High fever, pallor, severe jaundice terminally.	Red urine, hemoglobinuria.	Babesia in red cells in smear. Transmission test. Many serological tests.

Tropical Theileriosis *(Theileria annulata)*	Transmitted only by ticks of *Hyalomma* spp.	Fever, anorexia, lymph node enlargement.	Hemoglobinuria.	Piroplasms in red cells; schizonts in lymphocytes from liver biopsy. Serological tests. *Hyalomma* spp.
Postparturient hemoglobinuria	Postcalving 2–4 weeks. Adult dairy cows in 3rd–6th lactation. Sporadic but tends to endemicity on individual farms Low phosphorus or low copper diet.	Acute onset, weakness, tremor, pallor, bounding pulse, loud heart sounds, tachycardia. No jaundice. Mortality 50%. Long convalescence. Die of anemia, especially if stressed.	Deep brown to black frothy.	No cells in urine but good deposit on standing. Severe hemolytic anemia. Serum inorganic P<1.5 mg/dL and down to 0.1 mg/dL.
Bacillary hemoglobinuria	Summer time on irrigated pasture. Sporadic. Very few cases. Endemic to particular farms. Mortality 100%.	Often found dead. Very acute onset, hemolytic anemia plus toxemia. Fever 41°C (105°F). Abdominal pain, pain on percussion right anterior abdomen. Diarrhea. Shallow, rapid respiration due to diaphragmatic pain.	Deep red brown, no cells.	Hemolytic anemia, increased serum bilirubin.

Leptospirosis (*L. interrogans pomona* only, not *L. hardjo*)	Calves high mortality 50%. Adults low mortality <5%. Abortion storm more common in adults. Many subclinical infections in adults.	Hemolytic disease mostly in young calves. Sudden onset septicemia with red urine. Severe toxemia, fever 40.5–41.5°C (104.5–106°F). Mucosal petechiae, pallor and jaundice. Adults have thick orange milk all quarters.	Red urine, hemoglobinuria	Initially leptospiruria 3 day Leptospiruria by intraperitoneal injection into guinea-pigs. Rising titer leptospira antibodies with peak 4 weeks after infection.
Chronic copper poisoning	Rarely if at pasture. Copper supplement in a swine diet by mistake.	Sudden onset, weakness, pallor, jaundice, death usually in 24–48 hours.	Hemoglobinuria, some methemo-globinuria	High liver copper on biopsy 2000 ppm dry material. High plasma ceruloplasmin and copper.

26.1.8

TREATMENT

Primary treatment is aimed at destruction of the protozoa in the patient. Effective drugs are available for this purpose in cattle, but the initial phase of the disease is acute; if treatment is delayed for too long the animal may succumb to the anemia in spite of sterilization of the blood. When the illness is a consequence of vaccination with live vaccine, care must be taken to avoid complete sterilization of the blood before sufficient antibody is produced to provide a durable immunity. Treatment has no suppressing effect on the protozoa that are residing in the ticks parasitizing the cattle at the time.

A summary of the recommended drugs follows, but diminazene aceturate, imidocarb dipropionate, amicarbalide diisethionate, and phenamidine are most often used. Parvaquone, buparvaquone, and alovaquone are recent introductions with good reputations from clinical trials. Tetracyclines have been used extensively, but their use in acutely sick animals has been discontinued. They find some use in simultaneous administration with living babesia in a chemosterilant situation; the parasite is controlled but effective immunization is achieved.

26.1.8.1

Cattle

For many years, three babesicides, quinuronium sulfate and several generics of it, amicarbalide isoethionate, and diminazene aceturate were available in most countries for the treatment of bovine babesiosis. In the 1970s a fourth, imidodocarb dipropionate was introduced, and it rapidly became the drug of choice in those countries that licensed it, because in addition to its therapeutic utility, it also proved to be an effective prophylactic at twice the therapeutic dose.[2] Currently, it is the only babesicide on the market in most of Europe. Quinuronium sulfate and amicarbilide have been withdrawn because of manufacturing safety issues, and diminazene, which is widely used in the tropics as both a babesicide and a trypanocide, was withdrawn in Europe for marketing reasons.

1491 1493

Table 26.3 Differential diagnosis of anemia, with or without edema, in horses

Disease	Epidemiology	Clinical findings	Clinical pathology	Treatment
Anemia.				
Chronic blood loss	Sporadic. Parasitism. Intestinal blood loss e.g. gastric squamous cell carcinoma. Guttural pouch mycosis.	Lethargy, tachycardia, pale mucous membranes. Other signs consistent with underlying disease.	Hypochromic, microcytic anemia. Low serum iron concentrations. Increased serum iron binding capacity, and low serum ferritin concentration. Thrombocytopenia. Other results specific for underlying disease. Bone marrow – decreased myeloid: erythroid ratio	Correct underlying disease Administer ferrous sulfate 10–20 mg/kg per os once daily until serum iron concentration is normal and anemia has resolved.
Anemia of chronic disease (inflammation)	Sporadic. Associated with chronic, inflammatory disease (neoplasia, strangles abscess).	Lethargy. Signs consistent with underlying disease	Normocytic, normochromic mild anemia. Low serum iron concentration, low to unchanged total serum iron binding capacity, increased serum ferritin concentration. Bone marrow normal.	Treat underlying disease.
Aplastic anemia	Sporadic. Can occur as an outbreak in stables in which horses are administered recombinant human erythropoietin (rhEPO).	Lethargy, tachycardia, pale mucous membranes. Other signs consistent with underlying disease.	Normochromic, normocytic anemia. Normal to high serum iron concentration. Antibodies to rhEPO Bone marrow – very high myeloid to erythroid ratio due to lack of red cell series	Correct underlying disease. Prognosis for rhEPO-induced anemia is very poor.
Red Maple (*Acer rubrum*) intoxication	Ingestion of green or wilted leaves of red maple trees. Sporadic or several horses in one field. Regional according to distribution of tree.	Jaundice, hemoglobinuria, depression, colic, renal failure.	High (>1.5%) concentration of methemoglobin in blood. Heinz bodies in red blood cells.	Supportive care. Blood transfusion. Vitamin C suggested

Neonatal isoerythrolysis	Foals <4–5 days of age. Multiparous mares. Ingestion of colostrum containing isoantibodies to foal's red blood cells.	Weakness, depression, exercise intolerance, jaundice, hemoglobinuria.	Anemia, hyperbilirubinemia, positive Coombs test. Positive jaundiced foal agglutination test. Blood typing of mare and stallion and detection of isoantibodies in dam.	Conservative. Rest. Limit exercise. Severely affected foals require transfusion of blood or packed red cells from compatible donor.
Fell pony syndrome	Fell ponies <18 weeks of age. Suspected heritable defect.	Weakness, depression, ill-thrift, pneumonia, diarrhea and other opportunistic infections.	Normocytic, normochromic anemia. B-lymphocyte leucopenia. Decreased concentrations of immunoglobulins as foal's age.	None
Autoimmune hemolytic anemia	Secondary to other disease or drug administration. Penicillin-induced anemia	Depression, pallor of mucous membranes. Signs of underlying disease.	Anemia. Hemoglobinemia or hemoglobinuria. Coombs positive.	Corticosteroids or immunosuppressant drugs. Withdraw inciting cause.
Clostridial myonecrosis	Sporadic. Associated with intramuscular administration of medications or vaccinations.	Acute disease – fulminant myonecrosis with fever, depression and hemolytic anemia. Chronic disease associated with abscessation at site of injection, jaundice, hemoglobinemia, hemoglobinuria.	Anemia. Agglutination of red cells. Detection of IgM or IgG on red cell surface in chronic disease.	Treat underlying disease. Blood transfusion. Poor prognosis
Liver failure.	Sporadic. Associated with risk factors for liver disease.	Terminal phases of liver failure. Depression, weight loss, jaundice.	Consistent with liver disease (bilirubin, AST, bile acids, GGT).	None specific. Treat liver disease. Poor prognosis
Bone marrow hypoplasia in Standardbreds	Specific family line of Standardbred horses in North America.	Exercise intolerance, infections.	Anemia, pancytopenia	None.

Myelophthistic disorders	Sporadic. Bone marrow neoplasia (myeloproliferative disease, lymphosarcoma).	Exercise intolerance.	Depends on underlying disease. Normochromic normocytic anemia Profound leukocytosis in some diseases. Hypergammaglobulinemia	Treat specific disease.
Iatrogenic folate deficiency	Sporadic. Horses treated with drugs that inhibit folate metabolism and are administered synthetic folate orally, such as for treatment of equine protozoal myeloencephalitis.	Signs of underlying diseases. Unusual bacterial infection Depression, exercise intolerance, lethargy.	Mild anemia. Lymphopenia, neutropenia. Low blood folate concentrations.	Stop oral administration of folate. Administer folate parenterally.
Anemia with edema				
Babesiosis (*Theileria equi, Babesia caballi*)	Regional disease related to presence of vector ticks. Adult horses. Infected carrier state. *T. equi* transmitted transplacentally in addition to be tick bite.	Incubation period of 5–30 days. Depression, reluctance to move, recumbency, fever Dependent edema Colic. Mild jaundice and petechiation. Young horses most severely affected. Course 8–10 days.	*B. equi* in erythrocytes. Serologic testing using IFA or CF. PCR to detect organism.	Imidocarb
Equine infectious anemia	Virus. Acute disease followed by life-long infection. Insect vector (Tabanid flies) or mechanical transmission (veterinary instruments).	Acute disease of fever, anemia, dependent edema, and jaundice. Apparent recovery followed by intermittent relapses of usually less severe disease.	Thrombocytopenia. Anemia AGID (Coggin's) test. CELISA.	None specific. Control includes destruction of horses with a positive AGID or CELISA test in many jurisdictions.

Purpura hemorrhagica	Immune-mediated (antigen-antibody complex) secondary to respiratory disease. Adult horses. Sporadic occurrence.	Non-painful, cool, asymmetric subcutaneous swellings. Mild fever. Severe cases have multiple organ involvement including rhabdomyolysis.	Leucokytosis. Normal platelet count. High serum anti-streptococcal M protein antibody titer.	Penicillin. Corticosteroids. Supportive care.
Congestive heart failure	Sporadic.	Murmur of valvular insufficiency. Irregular heart rhythm (atrial fibrillation). Edema that is symmetrical, cool, and of dependent parts.	None specific.	None specific. Digitalis and furosemide in short term.
Strongylosis	Small strongyles (cyathostomes). Historically large strongyles.	Young horses. Mild fever, depression, diarrhea, edema.	Anemia, hypoproteinemia. In patent infestations fecal egg count.	Anthelmintics (ivermectin, moxidectin, benzimidazoles). Resistance an increasing occurrence.

Imidocarb is most toxic when given IV, and IM and SC administration is generally recommended. Side effects include coughing, muscular tremors, salivation, colic, and local irritation at the site of injection following high doses. While it is regarded as being slower in action than quinuronium sulfate it is the only babesicide that consistently clears the host of parasites. In the past, the persistence of small numbers of parasites in the bloodstream was deemed necessary for the maintenance of resistance to reinfection. However, the concept of premunition is no longer accepted. Premunition is used to describe resistance that is established after the primary infection has become chronic and is only effective if the parasite persists in the host. It was thought that only cattle actually infected with *Babesia* were resistant to clinical disease. If all organisms were removed from an animal, resistance was thought to wane immediately. However, cattle cured of *Babesia* infection by chemotherapy are resistant to challenge with the homologous strain of that organism for several years. But the presence of infection does appear to be mandatory for protection against heterologous strains.

While a certain period of antigenic exposure is necessary before treatment to facilitate the establishment of immunity, cattle treated with imidocarb dipropionate ultimately have a solid sterile immunity. Long-term persistence of low-level parasitemia is now considered a disadvantage. Remaining parasites may give rise to recrudescence under adverse conditions, treated cattle may act as a source of infection, and parasites surviving at low levels of babesicide may acquire resistance.

Imidocarb, provides protection from clinical disease for 3 to 6 weeks but allows a sufficient level of infection for immunity to develop. This strategy is highly effective if the host is assured to be exposed to babesiosis during the period of protection, either through a tick bite in areas where babesiosis is endemic or by inoculation of live parasites. Acquired immunity then takes over from the passive drug protection, and the animal passes smoothly to a resistant state without an intermediate clinical stage. However, if infection rates are sporadic of if very high doses of imidocarb are used, as a complete inhibition of parasite development will hinder the mounting of an adequate immune response. The major problem associated with this approach is concern about drug residues in milk and beef, which has led to the withdrawal of imidocarb in several European countries.[2]

26.1.8.1.1

Imidocarb (Imizol)

This, and the allied drug amidocarb, are effective babesicides for cattle at the dose rate of 1 mg/kg BW. At 2 mg/kg BW it completely eliminates the parasites from the host and maintains some residual activity; non-infected cattle derive a month's resistance to clinical infection but can therefore be used to protect cattle when vaccination is undesirable, e.g. pregnancy, or when exposure to infection is short lived, and as a temporary protection while awaiting vaccination. The drug can be given SC, but the hydrochloride is inclined to be irritant; the propionate is less so.

1493 1494

26.1.8.2

Horses and donkeys

The preferred treatment of equine babesiosis is not well-established. Many drugs have been used, but a combination of imidocarb and buparvaquone appears to be the only efficient treatment capable of eliminating *B. equi* infection. *B. caballi* is more susceptible, but it is expected to develop resistance quickly. **Imidocarb** must be given in a strict treatment regimen (four IM injections of 10% solution at a dose of 4 mg/kg BW at intervals of 72 hours). For *B. caballi*, a regimen of 2 mg/kg BW on two occasions 24 hours apart is sufficient to control an acute infection, but does not completely eliminate the

babesia, and the patient may become a carrier. The hydrochloride salt of imidocarb is strongly acidic and may provoke severe local reactions in horses, therefore, the dipropionate is being used more. A note of warning is necessary about the treatment of donkeys, which are very susceptible to imidocarb (the LD_{50} is less than 2 mg/kg BW). **Buparvaquone** 4–6 mg/kg BW parenterally is also capable of controlling acute babesiosis due to *B. equi*, but also on its own, like imidocarb, it does not eliminate the infection, allowing the horses to remain carriers. Some initial research has been done on the use of triclosan on equine and bovine *Babesia* infections.[48]

The therapeutic efficacy of imidocarb, artesunate, arteether, buparvaquone and arteether + buparvaquone combination was evaluated against *B. equi* of Indian origin in splenectomized donkeys with experimentally induced infection.[49] Imidocarb had deleterious effects on liver function, and the arteether + buparvaquone combination was found to be safe and may be a superior drug for treating *B. equi* infection.

26.1.8.3 Sheep

Diminazene aceturate is effective as a treatment in sheep (3.5 mg/kg BW on two successive days, or 12 mg/kg BW as a single dose).

26.1.8.4 Supportive treatment

In all species, treatment regimens for severely affected patients should include blood transfusions and anti-shock preparations. In chronic cases and convalescent patients, hematinics should be provided.

26.1.9 CONTROL (BOVINE BABESIOSIS)

26.1.9.1 Prevention and biosecurity

Prevention of introduction of the disease into a non-enzootic area depends on effective quarantine to prevent the introduction of the vector tick, and laboratory testing to ensure freedom of the importee from infection with the pathogen. The international movement of animals has become a very important matter to the horse industry where teams of pleasure horses attend competitions in other countries, and where valuable stallions move to another country for a brief period to stand at stud. There is a tendency for some countries to be very restrictive in their quarantine procedures for horses, and international relations would

be enhanced if more was known about the relationship between a positive serological test and infectivity for other horses.

26.1.9.2

Eradication

Eradication of bovine babesiosis from an area depends upon eradicating the vector tick – a problem in applied entomology. It was achieved in the United States but is unlikely to be attempted again because of the high cost to local wildlife, which are potential hosts to the ticks. Other problems encountered in the eradication process include:

- Difficulty of getting a complete muster of all cattle on every dipping day
- Multihost ticks, which can be infective but temporarily not resident on a beast on dipping day
- Spread of ticks or infested cattle due to environmental activity, e.g. floods, windstorms
- Illegal movement of cattle without a permit.

A major problem is encountered when the protozoan persists through succeeding generations of the vector tick. The resistance of ticks to acaricides is also a factor relating to the infestation level of cattle.[50]

The effect of three tick (*Boophilus microplus*) control strategies (none, threshold, and strategic) on endemic stability and the likelihood of babesiosis (*Babesia bovis*) has been examined using a spreadsheet age-class computer simulation model based on weekly tick counts from Brazil and Uruguay.[26] The Brazil bovine population was in a naturally occurring state of enzootic stability with an inoculation rate exceeding 0.005 throughout the year. Threshold dipping strategies did not increase the risk of babesiosis. Strategic dipping resulted in an extended period of enzootic instability lasting 30 weeks which required protection of the herd by vaccination. Because of the more prolonged low winter temperature conditions in Uruguay, the bovine population was in a naturally occurring state of endemic instability, characterized by a 28-week period in which the inoculation rate was below 0.005. Strategic dipping would lead to eradication of the babesial parasite from tick and bovine populations, but would not result in eradication of the tick vector. This could lead to subsequent outbreaks if *Babesia* carrier animals were introduced into the herd. In both populations, strategic tick control could be accompanied by concurrent babesiosis vaccination.

26.1.9.3

Limitation of prevalence

To accomplish limitation of prevalence at economically sustainable levels requires different solutions in different circumstances as set out below. It is largely dependent on tick control by the frequent application of acaricides, chemotherapy to kill the babesia in the cattle host and, to a lesser degree, by immunization of the host cattle. These measures are only partly effective, and are time-consuming and expensive. The reason for the poor performance of vaccination procedures after a great deal of research is that the mechanisms of immunity to protozoa, especially *Babesia* spp. is the lack of knowledge on how immunity to these parasites works.

- Susceptible cattle moving into an enzootic area need prior **vaccination**
- Marginal areas next to enzootic areas where tick populations vary with climatic change so that resident cattle lose their immunity after some dry years, and are then exposed to infection when wet years foster the migration of vector ticks back into the area. Recommended techniques are **vaccination** before outbreaks commence, if forecasting is available, plus temporary **chemoprophylaxis** after outbreaks have commenced
- Enzootic areas where losses are occurring due to environmental stress or, especially, concurrent infection with a second pathogen, e.g. *Anaplasma marginale*, or where the tick population has been decimated by overzealous dipping; **chemoprophylaxis** and relaxation of the dipping program are recommended. An adequate tick population is one ensuring that all cattle are infected and reinfected early and sufficiently often to maintain them in a state of constant of infection and therefore of immunity.

26.1.9.4

Vaccination

1494

1495

Vaccination has been done with varying degrees of success with live and dead whole parasites, crude parasite extracts, and isolated parasite antigens.[2] Several findings support the development of vaccines against babesiosis. First, cattle which recover from a primary *Babesia* infection or that have been immunized with attenuated parasites are resistant to challenge infection. Second, immunization of cattle with native *Babesia* antigen extracts or culture-derived supernatants containing secreted *Babesia* antigens elicit protective immunity against both homologous and heterologous challenge.

The features of cattle farms on which the exposure of young cattle to tick fever organisms is sufficient to ensure that immunity is high and the risk of clinical disease is low (see **endemic stability, under Epidemiology**) can be compared with those farms on which exposure is insufficient (endemic instability) can be compared to examine the relationships between the management of ticks and tick fever.[51] In Queensland, Australia, the majority of cattle herds do not have sufficient exposure to *B. bovis*, *B. bigemina* or *A. marginale* to confer endemic stability for tick fever.[51] For *B. bovis*, the major cause of outbreaks of clinical disease in Queensland, fewer than half the herds had evidence of endemic stability. The decision to leave a few ticks on cattle in an effort to induce endemic stability did increase the likelihood of endemic stability to *A. marginale*. However, it was ineffective, because only 26% of herds had endemic stability against all three organisms. Thus given the low proportion of herds with endemic stability to tick fever organisms and the high likelihood of clinical disease, vaccination is recommended to protect dairy cattle from tick fever throughout the tick-infested area of Queensland.

26.1.9.4.1

Vaccination with living immunogens

Vaccines incorporating live, attenuated strains of *B. bovis* and *B. bigemina* have been used routinely or experimentally in Australia and a number other countries.[52] The literature on designing blood-stage vaccines against *Babesia bovis* and *Babesia bigemina* has been reviewed.[36] The data available on the efficacy, degree and duration of immunity provided by live vaccines against *B. bovis* and *B. bigemina* infections in Australia have been reviewed.[53] Most of the available live vaccines are produced in government-supported production facilities, in Australia, Argentina, South Africa, Israel, and Uruguay. These vaccines include bovine erythrocytes infected with selected strains. The risk of contamination of blood-derived vaccine is real and makes post-production quality control essential, and unfortunately beyond the means of many countries in endemic regions. Techniques developed in Australia over many decades have formed the basis for production of live *Babesia* vaccines in most countries where they are used.[22]

26.1.9.4.1.1

Origin and purification of strains.

Since 1990, three strains of *B. bovis*, and one of *B. bigemina* (G strain) have been used to produce vaccines in Australia. After testing for virulence, immunogenecity and purity, suitable strains are preserved as master stabilates in liquid nitrogen.[22]

26.1.9.4.2 Attenuation of parasites

26.1.9.4.2.1 Babesia bovis.

The most reliable method of reducing the virulence of *B. bovis* is the rapid passage of strains through susceptible splenectomized calves. Attenuation usually occurs after 8 to 20 calf passages.

26.1.9.4.2.2 Babesia bigemina.

Rapid passage in splenectomized caves is not reliable but the virulence of *B. bigemina* decreases during prolonged residence in latently infected animals. A single *B. bigemina* isolate (G strains) has been used in the Australian and South African vaccines since 1972 and the early 1980s, respectively.[22]

26.1.9.4.3 Vaccine specifications

Live vaccines have proven very effective and reasonably safe, particularly when vaccination is restricted to cattle less than 1 year of age, when they still have natural resistance to the disease. Parasites for vaccines are derived from splenectomized donor calves infected with attenuated strains or parasites grown in vitro.[52] The vaccines are provided either chilled or cyropreserved. Despite the disadvantages, live vaccines provided greater than 95% protection for the life of the animals.

26.1.9.4.3.1 Frozen vaccine.

Frozen vaccine is superior to chilled vaccine because of long shelf-life which allows post-production testing of potency and safety before dispatch. Glycerol is used as cryoprotectant in Australia in preference to dimethyl sulphoxide because it allows post-thaw storage life of the vaccine for at least 8 hours. Frozen vaccine is the only product available in South Africa and Israel, and demand for it is growing in Australia. Frozen vaccines are transported in suitably insulated containers with liquid N_2 or solid CO_2 as refrigerant which limits the ability to supply vaccines to all destinations. To ensure infectivity, the prepared vaccine must be used within 8 hours of thawing, and once thawed should not be refrozen. If glycerol is used, a thawed vaccine can remain viable for only 8 hours at temperatures ranging from 4 to 30°C. A frozen bivalent *B.*

bovis and *B. bigemina* vaccine and frozen monovalent *B. bovis* and *B. bigemina* vaccines using dimethyl sulphoxide as the cryoprotectant are produced in South Africa and Israel, respectively. If dimethyl-sulphoxide is used, a vaccine should be used within 30 minutes of thawing.

26.1.9.4.3.2

Chilled vaccine.

Most of the babesiosis vaccines produced to date have been provided in a chilled form. In Australia, 35 million doses were supplied between 1996 and 2003. It is popular because of ease of production, ease of transportation even with limited resources, ease of use, and low cost. The chilled vaccines currently used in Australia contain 1×10^7 *B. bovis*, 2.5×10^6 *B. bigemina* and 1×10^7 *Anaplasma centrale* organisms per 2 mL dose. Chilled vaccine has a very short shelf-life, which is currently 4 days in Australia, which requires rapid, reliable means of communication and transportation to ensure viability. Chilled vaccines can remain viable for up to a week if stored at 4°C.

To reduce the risk of neonatal hemolytic disease in calves (**alloimmune hemolytic anemia**) of vaccinated dams, the vaccine should not be used repeatedly; most owners vaccinate only young animals seldom more than twice. Reduction of the dose rate from 5 to 2 mL and use of a cell free diluent has eliminated the problem in Australia.[22]

The procedures to ensure quality assurance of the vaccines has been described.[22]

The development of effective living vaccines against bovine babesiosis in Australia required laboratory and field research over the period from 1959 to 1996 is a remarkable success story of veterinary medicine.[54] The most significant change occurred in 1964 with the traditionally used carriers of *Babesia* being replaced as vaccine donors by acutely infected splenectomized calves. This ensured the infectivity of the vaccine and was fortuitously associated with a reduction in the virulence of the *Babesia bovis* vaccine. The vaccine reduced serious losses from babesiosis in vaccinated cattle in Australia to very low levels and gained acceptance worldwide.

The demand for live trivalent tick fever vaccine containing *B. bovis*, *B. bigemina* and *Anaplasma centrale* produced by the Department of Primary Industries, Queensland, has increased from less than 10000 doses in 1988 to 500000 doses in 2001.[55] The challenge to obtain *B. bigemina* parasitized erythrocytes on a large enough scale from infected splenectomized calves to meet the demand was achieved by reducing the dose rate of infected cells without affecting immunogenicity and still leave a safety margin

of at least 50-fold for infectivity. This change quadrupled the potential yield of doses per calf and allowed the Department to meet the increased demand for *B. bigemina* vaccine.

1495

1496

26.1.9.4.4

Use of live vaccine

26.1.9.4.4.1

Cattle born in vector-infested regions.

Any factor affecting the survival of the tick vectors will affect the risk of babesiosis occurring. An increased number of ticks will increase the threat of disease until an endemically stable situation develops. Conversely, reduced tick numbers will increase the longer-term risk of babesiosis due the reduced natural exposure of calves. Therefore, cattle owners in endemic areas in Australia are advised to supplement natural exposure by vaccinating calves at weaning age. Vaccination is also recommended if cattle are being moved within the endemic area.

26.1.9.4.4.2

Susceptible cattle imported into vector-infested country or region.

Large numbers of cattle, predominantly of *Bos taurus* breeds are being imported into tropical, developing countries to upgrade local livestock industries. This has resulted in significant economic losses due to tick-borne diseases, including babesiosis. Vaccination of naïve cattle moving from tick-free to endemic areas within Australia is usually very effective. This practice has played a crucial role in making the livestock industries in these countries more sustainable and competitive in meeting market demand with regard to breed type.

K strain *B. bovis* and G strain *B. bigemina* from Australia have been shown experimentally to be protective in South Africa and Sri Lanka. Vaccine containing these strains has also been used with beneficial results in countries such as Zimbabwe and Swaziland in Africa, Venezuela and Ecuador in South America, Malaysia and the Philippines in Southeast Asia, and islands of the Caribbean.

26.1.9.4.4.3

Control of outbreaks.

Use of a vaccine in the face of an outbreak is common practice in Australia.[22] Superimposing vaccination in this way on a natural infection will not exacerbate the disease, but will pre-empt the development of virulent infections in the proportion of

the herd not yet exposed to field challenge. To prevent further exposure, the group should also be treated with an acaricide capable of preventing tick attachment from the time of diagnosis to 3 weeks after vaccination. Injectable or pour-on formulations of ivermectin and moxidectin as well as fluazuron are highly effective acaricides but do not prevent transmission of *Babesia*.

Clinically affected cattle should be treated as soon as possible with a suitable babesiacide. In the case of a severe outbreak, it may be advisable to treat all the cattle with a prophylactic compound (imidocarb or diminazene) and to vaccinate them later when the drug residue will not affect vaccine parasite multiplication.

26.1.9.4.5

Hazards and precautions of live vaccine use

26.1.9.4.5.1

Severe reactions.

The likelihood of vaccine-induced reactions has been reduced with the development of attenuated strains but there is always the risk of reactions when highly susceptible, adult cattle are vaccinated. Calves 3 to 9 months of age have a high level of natural resistance and a low risk of reactions. In Argentina, vaccination is only recommended for calves while in Australia and South Africa, adult cattle can be vaccinated, provided proper precautions are taken. Concurrent infections may increase the likelihood of reactions.[22] The fever associated with reactions in pregnant cows may cause abortion and in large bulls a temporary loss of fertility. In the case of valuable cows and bulls, their body temperatures should be monitored during the reaction and those with prolonged fever should be treated with a babesiacide.

26.1.9.4.5.2

Potential for spread of Babesia following vaccination.

There is no reliable evidence that current live vaccines may spread the disease from vaccinated to unvaccinated cattle.[22]

26.1.9.4.5.3

Lack of protection.

Since the introduction of a standardized method of production in Australia, live babesiosis vaccines have generally proved to be highly effective. In most cases, a single vaccination provided lasting, probably life-long immunity against field infections with antigenically different strains. However, some failures have occurred and are thought to be associated with loss immunogenicity by frequent passaging of

the vaccine strains in splenectomized calves. This was corrected by replacing the vaccine strain. To prevent future recurrences of failure, the number of passages of the vaccine strains of *B. bovis* is limited by frequently reverting to a master stabilate with a low passage number. Other failures may be associated with the immune responsiveness of the host and the immunogenicity of the vaccine strain subpopulations.

A single inoculation of an attenuated vaccine containing *B. bovis* and *B. bigemina* at 6 to 9 months of age provides good, long-lasting protection both in Australia and overseas.[53] At that age, the risk of vaccine reactions is minimal. The immunity following use of live *B. bovis* vaccine lasts for at least 4 years, and possibly less for *B. bigemina*.[52] It is known to persist even after elimination of *Babesia* infections and studies on drug cured cattle suggest that the degree of acquired immunity is related to the degree of antigenic stimulation (duration of prior infection) rather than the presence of live parasites. There is no evidence of a loss of immunity with time and revaccination is unnecessary. Revaccination is advisable when there is uncertainty over the accuracy of previous procedures, to ensure all animals seroconvert or when there has been a change in the strains used in the vaccine.

An attenuated frozen vaccine containing in vitro culture-derived stains of *B. bovis* and *B. bigemina*, provided protection to 90% of vaccinated cattle against the virulent *Babesia* spp. field strains.[56]

The persistence of *Babesia bovis* and *B. bigemina* infection in Friesian cows, following vaccination with attenuated live vaccines has been shown by subinoculation of blood into splenectomized calves.[40] *B. bigemina* persisted in some cows vaccinated 10 and 46 months, previously, and *B. bovis* persisted in 50% of cows vaccinated 10 and 47 months previously. Parasites of both species persisted among the serologically negative cows, whereas blood obtained from serologically positive cows failed to transmit infection. Thus in the absence of reinfection, Friesian cattle may spontaneously eliminate *B. bigemina* and *B. bovis* infection after various periods of time.

The inherent disadvantages of vaccines derived from blood of animals include the risk of reactions or contamination with pathogenic organisms, sensitization against blood groups, tick transmissibility of vaccine strains and need for a **cold chain transportation**.

Vaccinated cattle should be housed or kept under close observation for a month in case excessive reactions occur. A major problem in vaccination with living protozoa is the occasional apparent **failure to transmit the protozoa**. This may be due to the absence of the protozoa from the bloodstream of the donor at the time that the blood is drawn, or to the presence of a prophylactic drug – for example, imidocarb dipropionate – or low levels of antibody in the animal's tissues. Revaccination is necessary in these circumstances, preferably with blood from a donor that is undergoing a severe reaction at the time.

The attenuated organisms used in unfrozen South Africa *B. bovis* and *B. bigemina* vaccines are susceptible for longer periods to the residual effect of the anti-babesial drugs diminazene and imidocarb dipropionate than the virulent field strains. The waiting periods before administration of the frozen *B. bovis* and *B. bigemina* vaccines in animals which have been treated with diminazene at 3.5 mg/kg BW, compare favorably with unfrozen vaccines at 4 and 8 weeks. The inhibitory effect of imidocarb dipropionate at 3.0 mg/kg BW on the infectivity of both frozen *B. bovis* and *B. bigemina* vaccines is longer, and requires minimum waiting periods before administration of these vaccines of 12 weeks and 24 weeks, respectively.[57] 1496 1497

26.1.9.4.6

Vaccination with subunit vaccines

Subunit vaccines offer an attractive alternative to virulent or attenuated parasites.[58] The vaccines are based on recombinant antigens derived from cloned DNA of protozoan parasites.[58] Several protective antigens associated with merozoites or merozoite-infected erythrocytes of *B. bigemina* and *B. bovis* have been identified as possible approaches.[58] Rhoptry-associated proteins may become the first targets of generic recombinant vaccines.[2]

26.1.9.4.7

Non-living vaccines

Non-living vaccines would overcome many of the inherent difficulties in production, transport and use of live vaccines.[22] However, they have not been sufficiently efficacious and more research is required.

26.1.9.5

Vector control

Vector control was first used successfully to control and eventually eradicate the cattle tick *Boophilus annulatus* and *Babesia* from the United State.[59,60] In 1906, an eradication program began which involved livestock owners, state officials, and the US Department of Agriculture specialists.[60] The program involved three tactics. First, some pastures were rendered tick-free by excluding all host animals until the ticks had starved to death. The second and more common tactic was to retain the livestock on the infested pastures and to disinfect the animals at regular 2-week intervals by immersion in an arsenic solution which killed the engorged female ticks. Third, the interstate movement of tick-infested cattle was prohibited through quarantine. The campaign to eradicate cattle ticks from the United States is the most sustained, extensive, coordinated area-wide attack ever made against an arthropod pest. The tick was removed from over a million square km during a period of 34 years. The tick is confined to the lower Rio Grande River in Texas, where reinfestation occurs via animal movement from Mexico. This necessitates continual control of fringe populations of cattle.

In Africa, babesiosis is only part of very important complexes of ticks and tick-borne disease, and intensive government-regulated tick control programs have been used for many years. In other continents, the situation is much less complex and where babesiosis is endemic, disease control rather than eradication is more realistic. Eradication of the tick vectors is a permanent solution to the problem but is rarely considered practical, environmentally sustainable, or economically justifiable on either a national or a local basis.

26.1.9.6

Natural endemic stability

Natural endemic stability can seldom be relied upon on as a disease control strategy. First, in endemic areas, climatic effects, genetic make-up of hosts and management strategies, inevitably have a major effect on the rate of transmission and ultimately on the likelihood of endemic stability developing. Second, endemic stability is an economic concept that incorporates risk management and loss thresholds. The climatic, animal, and management parameters which allow endemic stability can change on a seasonal and annual basis. Third, the model for endemic stability was developed in Australia and the Americas where disease/vector interactions are relatively simple. The African situation is much more

complex and less predictable with four main diseases, several vectors, presence of game reservoirs, and larger range of susceptibility of bovine breeds.[22]

26.1.9.7

Control of babesiosis in species other than cattle

For the most part, control of babesiosis in other species is carried out similarly to the procedures used in control of the disease in cattle. Most attention is focused on eradicating the vector tick, selecting infected and carrier animals by an appropriate laboratory test, and sterilizing the positive reactors by appropriate treatments. Control of ticks in pleasure horses by periodic spraying and inspection is a practical proposition when the animals are in constant use. No vaccines have been produced for use in horses. An attenuated vaccine produced by rapid passage through splenectomized lambs produces solid immunity in sheep.

1498

26.2 COCCIDIOSIS

26.2.1 Synopsis

26.2.1.1 Etiology

Many different *Eimeria* spp., *Isospora* spp.

26.2.1.2 Epidemiology

Young calves, lambs, piglets, kids and, rarely, foals. Infection rate is high, clinical disease much less common; high morbidity with low case fatality rate. Occurs most commonly in crowded conditions both in barns and on pasture, especially in calves and lambs moved from pasture to feedlot. Transmitted by fecal – oral route; oocysts shed from infected animals. Immunity develops after infection; clinical disease occurs rarely in adult cattle.

26.2.1.3 Signs

Diarrhea, dysentery, tenesmus, appetite normal or inappetence, mild abdominal pain in lambs, nervous signs in calves with coccidiosis in cold climates, loss of body weight, anemia in some cases but not common. Epidemics occur in calves and lambs, especially feedlot animals. Diarrhea without blood in feces of piglets. Diarrhea with large amount of blood in foals.

26.2.1.4 Clinical pathology

Diagnostic number of oocysts in feces.

26.2.1.5 Lesions

Ileitis, cecitis, colitis.

26.2.1.6 Diagnostic confirmation

Oocysts in feces; merozoites in intestinal tissues.

26.2.1.7 Differential diagnosis

26.2.1.7.1 Calves:

Rotavirus and coronavirus diarrhea; *Clostridium perfringens* Type C enterotoxemia; colibacillosis due to attaching and effacing *Escherichia coli*.

26.2.1.7.2 Lamb:

Salmonellosis; helminthiasis; *Clostridium perfringens* Type C enterotoxemia.

26.2.1.7.3 Piglets:

Transmissible gastroenteritis; colibacillosis; *Strongyloides ransomi*; *Clostridium perfringens* Type C enterotoxemia.

26.2.1.7.4 Foals:

Salmonellosis; Foal-heat diarrhea; Rotavirus diarrhea; *Clostridium perfringens* type B enterotoxemia.

26.2.1.8

Treatment

Supportive therapy. Coccidiostats.

26.2.1.9

Control

Control population density to minimize number of oocysts ingested while immunity develops. Use of coccidiostats in feed and water supplies.

26.2.2

ETIOLOGY

The pathogenic coccidial species are as follows:

- **Cattle:** *Eimeria zuernii, E. bovis* (*smithii*) and *E. ellipsoidalis*. *E. alabamensis*,[1] *E. auburnensis* and *E. wyomingensis* may also cause disease in calves
- **Sheep:** *E. arloingi* A (*ovina*), *E. weybridgenis* (*E. arloingi* B), *E. crandallis*,[2] *E. ahsata* and *E. ovinoidalis* (previously known as *E. ninakohlyakimovae*)[2] and *E. gilruthi*[3]
- **Goats:** *E. arloingi, E. faurei* and *E. gilruthi, E. caprovina*, *E. ninakohlyakimovae*[1] and *E. christenseni*
- **Pigs:** *Isospora suis, E. debliecki*, *E. scabra* and *E. perminuta*
- **Horses and donkeys:** *E. leuckarti*.[4]

The eimeriid coccidia are one of the more controversial groups of protozoa, and their taxonomy and classification have been debated for more than 50 years.[5] A Controversial Roundtable was held in 2001 to initiate discussion on how a new and more comprehensive classification of eimeriid coccidia can be devised.

26.2.3

EPIDEMIOLOGY

26.2.3.1

Occurrence and prevalence of infection

Coccidiosis occurs universally, most commonly in animals housed or confined in small areas contaminated with oocysts. The coccidia are host-specific and there is no cross-immunity between species of coccidia. Clinical disease is most common in cattle and

sheep. Coccidiosis causing diarrhea in newborn piglets is a major problem in some swine herds. Coccidiosis is less common in horses, but sporadic clinical cases and deaths do occur, especially in weaning age foals.

Coccidiosis occurs most commonly in young animals, with a seasonal incidence that may be associated with the time of year young calves and lambs are brought together for weaning or moved into feedlots or fed in small areas for the winter months. The prevalence of infection and the incidence of clinical disease are also age related. In housed dairy cattle, the prevalence of infection is 46% in calves, 43% in yearlings, and 16% in adult cows.[6]

26.2.3.2

Calves

In North America, the disease occurs most commonly in beef calves after weaning in the fall of the year and when confined and fed in small overcrowded areas during the winter months. Infection occurs commonly when weaned calves are fed on the ground resulting in continuous fecal contamination of the feed. The prevalence of infection in calves in the northwestern and midwestern part of the United States is highest in summer, fall and spring compared to midwinter (January) and early summer (June). In Canada, winter coccidiosis occurs in beef calves 6–10 months of age most commonly following a prolonged cold period or a sudden change from a moderate winter to severely cold temperature.[7] Cold weather may act as a stressor to precipitate clinical disease in animals previously infected. Acute coccidiosis and a marked increase in the numbers of oocysts discharged will occur following the treatment of infected calves with a corticosteroid on the 20th day after infection when clinical signs are apparent, or from the 12th–15th day after infection.[8]

Occasional outbreaks occur in nursing beef calves on pasture when they mingle near water supplies. Post-weaning coccidiosis occurs in beef calves grazing pasture in the subcostal dry tropics of northern Queensland, Australia. It may be more severe in dry years suggesting that the oocyst challenge is less important than the immunosuppressive effect of weaning and dietary stress in precipitating clinical disease. Calves are usually weaned and yarded for 3 weeks and then turned out to graze. Severe *Eimeria zuernii* coccidiosis causing diarrhea, dysentery, weight loss, and death occurs with up to 10% of calves being clinically affected. The disease is most severe in hot, dry and sunny conditions when, despite heavy fecal contamination, the yard conditions remain dry and dusty, and oocysts are difficult to find.

In South Africa, the prevalence is highest in calves and the most prevalent species are *Eimeria zuernii*, *Eimeria ellipsoidalis*, and *Eimeria bovis*.[9] The oocyst levels in the feces of adult cows were low.

In Sweden, coccidiosis due to *E. alabamensis* along with other species is a common cause of diarrhea and unthriftiness in calves 2–4 months of age within the first few weeks after being placed on permanent pasture in the spring.[11] The onset of the diarrhea coincides with the prepatent period of 6–8 days of *E. alabamensis*. Overwintered sporulated oocysts of several different species are the source of infection.[10] The incidence of diarrhea is much higher in first-season grazing calves placed on pastures that had been used for cattle in the previous 5 years compared to those calves placed on different pastures not previously used by cattle.[9] The likely primary source of infection is the calves or previous occupants of pens, with the mature cows being unimportant.[12] Clinical coccidiosis can be reproduced by inoculation of calves with a pathogenic dose of *E. alabamensis*,[13] and is most severe in calves receiving the highest number of oocysts.

1498

In **dairy calves**, the disease occurs in overcrowded and dirty, wet conditions, and when 1499 fecal contamination of the feed is common. Surveys of dairy farms in Pennsylvania reveal that coccidiosis was found the third most common health-related problem observed by dairy farmers.[14] Over 16% of dairy farmers were treating animals, or feeding a coccidiostat, for the control of coccidiosis.

26.2.3.3

Adult cattle

Coccidiosis is uncommon in adult cattle, but occasional cases and even epidemics do occur, especially in dairy cows that have calved 6–8 weeks earlier.[3] Surveys of farms in Maryland found that 2.3% of dairy cows, 21.7% of dairy heifers, and 32.9% of beef cattle were all infected with *E. bovis* and all were subclinical.[15] These older animals serve as source of infection for younger calves in the herd.

26.2.3.4

Lambs

Coccidiosis in lambs is a common disease in housed flocks.[16] In Germany, the cumulative incidences of *E. ovinoidalis* and *E. weybridgensis*/*crandallis* increased rapidly resulting in almost 100% incidence in 8 week-old lambs.

Acute coccidiosis in intensively grazed lambs in Britain occurs at about 6–8 weeks of age when the oocyst output is very high in healthy, as well as in clinically affected, lambs. There is no periparturient rise in oocyst output by the ewes. The oocyst output by grazing lambs is very large compared to the output by ewes.

Coccidiosis occurs commonly in lambs following introduction into a feedlot situation where overcrowding and other stressors are operative. Lambs moved directly from range have had almost no previous exposure to coccidia, making them highly susceptible to infection and outbreaks of clinical disease. Coccidiosis is also a major problem in rearing housed lambs in the United Kingdom.[17]

26.2.3.5

Goats

Coccidiosis is one of the most important diseases of goats kept in large numbers under intensive management conditions.[18] The prevalence of infection may be as high as 100% in some goat farms, and higher infection rates occur in young goats in large herds.[19] Kids are the major source of pasture contamination, and newly weaned kids have high oocyst counts.[20] Over 13 different species of coccidia have been identified in goats from different parts of the world. Surveys in Zimbabwe reveal a population mortality of 20–40% among kids on different farms; coccidiosis is thought to be a major cause of these deaths.[18] Coccidial and helminth infections may occur concurrently in goats of varying ages surveyed on farms but nematode infections do not occur in kids.[21] Goat kids concurrently infected with third-stage *Haemonchus contortus* may gain weight more slowly.[22] Goats do not shed as many oocysts and helminth eggs as do sheep,[23] which may be related to their mode of feeding (browsing versus grazing).

In the Czech Republic, where the majority of goats are dairy goats, the overall prevalence of *Eimeria* oocysts in feces was 92%.[24] Nine *Eimeria* spp. were identified and *E. arloingi* was the most common with a prevalence of 84%. The number of oocysts was lower in adults and the highest in kids and clinical coccidiosis occurred in kids 2 to 4 weeks after weaning. The disease occurs in goats in Poland where 81% of adults and 100% kids are infected, and clinical coccidiosis occurs in 50% of the kids.[25] In West African Dwarf goats in Ghana, *Eimeria* oocysts appeared at about 20 days after birth and oocyst output in some kids reached 2.7 million oocysts per gram of feces by about 39 days after birth, followed by declines to 23 840 per gram by 5.5 months of age.[26]

26.2.3.6

Pigs

Observations suggesting the presence of neonatal porcine coccidiosis include: repeated epidemics of diarrhea in piglets 5–15 days of age; no response to therapy with antimicrobials; and failure of vaccination of the pregnant sow with *E. coli* bacterins to control neonatal piglet diarrhea. The peak incidence occurs between 7 and 10 days of age, and most commonly during the warm summer months when high temperatures favor the sporulation of the oocysts. *Isospora suis* is a common parasite on pig farms; it may be found in 90% of herds and from 25 to 50% of litters.[27,28] The prevalence may be higher when piglets and their sows are raised on solid cement floors compared to self-cleaning floors.[27] The morbidity rates are variable and the case fatality rates may be up to 20%. Rotavirus infection may occur concurrently with *Isospora suis* infection in piglets 1–3 weeks of age and may be important causes of steatorrhea, or unspecified diarrhea known as milk scour, white scour, or 3-week diarrhea. Coccidiosis associated with *E. scabra* has also occurred in a 40 kg finishing pig affected with severe diarrhea and weight loss, and an outbreak of severe enteritis with dysentery in grower pigs from 7 to 16 weeks of age, due to a mixture of *Eimeria* spp. including *E. porci* has occurred. Coccidiosis has occurred in 20-week-old gilts moved from a high health status environment to a dirt lot, which suggests that high-health-status pigs are highly susceptible to coccidiosis.[29]

I. suis infection occurs widely in large pig-producing farming systems in Germany where the highest rate of infection occurs in litters at 3 to 4 weeks of age.[30] Surveys of intestinal parasites in pigs from intensive farms in China have found *I. suis* infections along with other parasites.[31]

Surveys of pig farms in Germany, Switzerland, and Austria found 76% of the farms were positive for *I. suis* and oocysts were more commonly found on farms which reported diarrhea and uneven weight gain. Disinfection, floor types or treatment with toltrazuril did not affect the frequency of observations.[32]

26.2.3.7

Foals

Eimeria leuckarti is a ubiquitous protozoal parasite of horses that has been reported in North America and elsewhere. In a survey of horse farms in Kentucky, 41% of foals examined were oocyst-positive, and 85% of farms had oocyst-positive foals.[4] The

incidence of clinical disease is much less common in foals than other species, but clinical cases and deaths do occur, particularly in recently weaned foals.

26.2.3.8

Morbidity and case fatality

In general, for **most species** of farm animals, the infection rate is high, and rate of clinical disease is usually low (5–10%), although epidemics affecting up to 80% may occur. The case fatality rate is usually low, with the exception of the high case fatality rate in calves with winter coccidiosis accompanied by nervous signs.[7] The case fatality rate may be high in calves or lambs with no previous exposure to coccidia after suddenly being introduced to a high level of infection. In calves, body weight gains and feed consumption are commonly reduced for many weeks after acute clinical coccidiosis, and affected calves do not regain losses in body weight compared to controls.

In **lambs on pasture**, subclinical infections are common but there is no documented evidence that growth rate is affected even with high levels of infection. While medication with a coccidiostat may lower the infection rate, there is no difference in performance between the medicated and non-medicated groups. In lambs raised under crowded conditions indoors, the acquisition of a natural multiple species infection had no effect on growth rate, but an artificial infection with *E. ninakohlyakimovae* resulted in severe clinical disease and a case fatality rate of 50%.

Piglets infected with *I. suis* have significantly reduced body weight at 7, 14, and 21 days of age. The reduction in 21-day-old weight is economically important because this weight is a component of the sow productivity index which is used as a management aid to help producers quantitatively determine the potential value of gilts as replacement animals.

1499

1500

26.2.3.9

Methods of transmission

The **source of infection** is the feces of clinically affected or carrier animals, and infection is acquired by ingestion of contaminated feed and water, or by licking the hair coat contaminated with infected feces. Oocysts passed in the feces require suitable environmental conditions to sporulate. **Moist, temperate, or cool conditions favor sporulation, whereas high temperatures and dryness impede it.** In general, oocysts sporulate at a range of 12–32°C (53.5–89.5°F) and require oxygen. They resist freezing down to about – 7 to – 8°C (19.5–17.5°F) for 2 months, but – 30°C (–22°F) is usually lethal.[33] It has been suggested that oocysts might sporulate in the winter months on the hair coats of animals contaminated with feces. This may explain the continual production

of several different species of coccidia during the cold winter months when sporulation on the ground is not possible.[33] Dry conditions and high temperatures also destroy sporulated oocysts within a few weeks but the oocysts may survive for up to 2 years under favorable conditions. Temperatures above 35°C, humidity below 25%, and sunlight for 4 hours are fatal for *E. zuernii*. Under simulated yard conditions in Queensland, Australia, where it is hot, dry, and sunny, when the yard floor materials reach up to 48°C and when air temperatures did not exceed 27°C, oocyst numbers fall by 50% after 24 hours, by 98% after 48 hours, and are undetectable after 72 hours.[33]

Ingestion of the sporulated oocysts results in infection, but very large numbers must be taken in before clinical disease results. **Large numbers of oocysts arise by continual reinfection and building up the degree of environmental contamination.** This occurs commonly when calves or lambs are crowded into small pens or confined in feedlots. Lambs can become infected within a few weeks after birth from lambing grounds heavily contaminated by the ewes. Overcrowding of pastured animals on irrigated pasture, or around surface water holes in drought conditions, may also cause heavy infestations. Feeder lambs and calves brought into feedlots from sparse grazing may carry a few oocysts, which build up into heavy infestations in the lots, especially if conditions are moist. In such situations, clinical signs of the disease usually appear about a month after the animals are confined. Young calves and lambs on pasture may shed large numbers of oocysts for long periods, which may be a factor in the development of large coccidial populations.

In cow-calf herds in Germany, the prevalence and intensity of oocyst excretion varied with time resulting in peak values around the time of parturition (periparturient rise), particularly in the case of *Eimeria bovis*.[34] Oocysts of *E. zuernii*, *E. auburnensis* were first observed in calves 3 weeks of age and the prevalence of infection increased up to 67% by 9 weeks of age. The serum antibody levels in the cows were inversely correlated with *E. bovis* oocyst excretion which may reflect the degree of immunity developed against the infection in the cows. Antibodies to *E. bovis* were present in the sera calves after the ingestion of colostrum; the levels decreased from the first week of life until the third week. Subsequently, antibody levels increased until 9 weeks of age in direct correlation with oocyst excretion.[34]

Lambs may become infected soon after birth (before 4 weeks of age) from three possible sources of infective oocysts:

- Oocysts surviving in old fecal contamination of the lambing area from previous occupation
- Fresh oocysts constantly shed by ewes
- Fresh oocysts shed by other lambs.

The fecal oocyst burden is high at 4 weeks of age but gradually declines, so that by 5 months of age the oocyst count is similar to that of their parent ewes.

Sows do not play a significant role in the transmission of *I. suis* infections transmitted from one generation of piglets to the next through contamination of the farrowing pen. Infection levels as low as 100 sporulated oocysts can result in oocysts per gram values of 100 000 and induce clinical signs of coccidiosis within 2 weeks of infection.[35] Oocysts of *I. suis* cannot usually be found in the feces of sows on swine farms where neonatal coccidiosis occurs. In one survey, no oocysts of *I. suis* were found in sows on farms with a history of neonatal coccidiosis due to *I. suis*, but 82% of the sows were infected with *Eimeria* spp. On farms without a history of neonatal coccidiosis, the prevalence of *I. suis* in the sows was 0.6%. In a survey in Papua New Guinea, 83% of sows raised on concrete were infected with *I. suis*. In another study, of two swine herds where neonatal coccidiosis due to *I. suis* occurred, the sows either began to excrete oocysts, or oocyst excretion rose to a detectable level from 5 days before to 3 days after farrowing. The oocysts of *I. suis* can sporulate and become infected within 12–16 hours at temperature ranges of 32–35°C (89.5–95°F), which are common in modern farrowing units.

26.2.3.10 ## Risk factors

26.2.3.10.1 ### Animal risk factors

Acute coccidiosis occurs primarily in **young animals**, but may occur at any age when resistance is affected by intercurrent disease or inclement weather. The prevalence of infection is usually higher in calves than yearlings or adults in the same herd, but there is also evidence of variation in *Eimeria* species-specific age resistance.[6] A concurrent experimental infection of calves with the coronavirus and *E. bovis* may result in clinical disease and lesions that are more severe than those caused by either infection alone.[36]

Nutritional status of the animal as a risk factor for clinical coccidiosis is well known. Early weaning of lambs at 21 days of age, followed by experimental infection, results in

a failure of growth. Field observations have shown that early weaned lambs are more susceptible to coccidiosis than those weaned at a later date. This may be a reflection of lack of immunity in the younger lambs, but dietary stress in early weaned lambs may contribute to the disease. In sheep with naturally occurring coccidiosis, animals on moderate and high planes of nutrition may have more dual infections than those on a low plane of nutrition, whereas the latter group have triple and quadruple infections. Considerable numbers of oocysts can be excreted into the environment even by well-fed sheep of 14–16 months of age. Lambs kept on a low plane of nutrition were less affected by clinical coccidiosis than those kept on a high plane of nutrition. The planes of nutrition were also associated with differences in the prevalences of *Eimeria* spp.

In the United Kingdom, coccidiosis occurs commonly in **housed lambs weaned at 6–8 weeks of age** and reared on straw with a high stocking density, which provides an ideal environment for oocyst survival and sporulation.[17] The use of coccidiostats does not affect the oocyst excretion rate, which suggests either inconsistencies in the effect of in-feed medication or the infection may be controllable in non-medicated flocks without the use of coccidiostats.

Epidemics of post-weaning coccidiosis occur in beef calves under hot and dry tropical conditions where the ingestion of oocysts is small because the conditions are unsuitable for oocyst development. Such calves have usually commenced shedding oocysts within a month of birth and can shed up to nine different species by 3–4 months. Calves developing clinical coccidiosis following weaning may be more physiologically susceptible than others.

26.2.3.10.2

Environmental and management risk factors

Coccidiosis occurs in all species of farm animals when environmental and managemental conditions result in **oral exposure** of large numbers of sporulated oocysts to non-immune animals. Overcrowding and feeding animals on the ground, or in situations in which the feed and water supplies can become heavily contaminated with feces and oocysts increases the infection pressure and promotes the fecal–oral route cycle of infection. The disease occurs commonly in small beef cattle herds that raise their own replacements and finish their own feedlot cattle in small outside pens that are crowded, and the feed becomes heavily contaminated by feces. Grazing calves for the first time on permanent pastures is associated with clinical coccidiosis due to the ingestion of overwintered oocysts.[1]

1500 1501

The occurrence of clinical coccidiosis in housed dairy cattle in The Netherlands is rare.[6] This may be associated with management practices in which calves are individually housed during the first few weeks and subsequently housed in small groups in relatively large pens. General hygienic standards are high, and manure is frequently removed. These measures reduce the intake of high numbers of oocysts and are favorable because the intensity of coccidial infections is directly related to the number of oocysts in the environment and ingested by the animals. A low level of oocyst infection will induce immunity.

The production system can influence the development of subclinical and clinical coccidiosis. In Germany, two production systems of fattening lambs are common. In the extensive system, lambs are not weaned until slaughter with little or no concentrate feeding. In the intensive system, the lambs receive a high level of concentrates.[37] In lambs naturally infected with *Eimeria* spp., the mean fattening period was significantly shorter in the intensively managed groups compared with an extensively managed group. Even if no clinical signs of coccidiosis were observed in any of the systems, based on reduced daily weight gains, the lambs were subclinically affected by coccidiosis in all systems. The highest oocyst output occurred in the extensive group which may be related to intake of straw and hay from the ground. Straw and high stocking density predispose a heavy contamination of an environment which is ideal for oocyst survival and rapid sporulation. The risk of coccidiosis increased markedly if animals have a higher intake of contaminated straw from the ground.

26.2.3.10.3

Pathogen risk factors

Multiple infections are most common in natural infections. A single species of coccidia may be the major pathogen, but others contribute to the disease. In some cases, clinical coccidiosis in cattle occurs only when *E. bovis* and *E. zuernii* occur together. At least 13 species of coccidia oocysts have been found in the feces of cattle in the United States, with *E. bovis* being the most prevalent. In sheep and goats, the prevalence of multiple species can be as high as 95% and 85%, respectively. In a single sheep flock, there may be as many as 10 species of *Eimeria*.[38] *E. ovinoidalis, E. ovina, E. ahsata*, and *E. parva* are highly pathogenic, whereas *E. faurei, E. intricata, E. crandallis*, and *E. weybridgensis* are only moderately pathogenic. Similar results have been obtained in surveys done in feeder cattle brought from different geographical locations in the United States to a feedlot. While *E. bovis* and *E. zuernii* are the species most commonly

associated with bovine coccidiosis, as many as 11 different species may be present in the cows and calves of one beef herd. *I. suis* is a major cause of neonatal or weanling diarrhea in pigs, while *E. debliecki* is not considered a pathogen. This provides evidence that coccidia have a widespread distribution wherever animals are kept.

26.2.3.11

Immune mechanisms

Immunity against intestinal coccidia consists of both cellular and humoral components. Cellular immunity is more important in resistance against reinfection than humoral immunity. Field observations suggest that coccidiosis in cattle is immunosuppressive, which may increase their susceptibility to other common infections. In experimental coccidiosis, neutrophil function may be inhibited and the feeding of decoquinate may prevent this inhibition.

The administration of dexamethasone to calves suppresses the immunological response of the animal and allows the life cycle of the coccidia to proceed uninterrupted.[8] Estradiol and progesterone can enhance cell-mediated immunity and provide some protection against the often severe wasting and debilitation in calves associated with *E. bovis* infection.[39]

In Norway, coccidiosis is an important disease in young lambs on pasture. Most lambs spend the first few weeks of their life indoors and have little exposure to infective oocysts, and little or no immunity is acquired. When the lambs are turned out to pastures grazed by sheep in the previous grazing season, they rapidly become infected with overwintered oocysts, mainly as a result of their habit of eating soil. Coccidiosis develops in these non-immune lambs 2–3 weeks later. The immunity induced by the first infection seems to protect most lambs from reinfections later in the grazing season. In lambs treated with sulfadimidine at 200 mg/kg BW on days 12, 13, and 14 after turnout, there is a marked reduction in the severity of the coccidial infections.

Specific immunity to each coccidial species develops after infection, so that young animals exposed for the first time are often more susceptible to a severe infection and clinical disease than other animals. In lambs, natural infection acquired at pasture and artificial infections acquired by experimental inoculation result in immunity to challenge. A single initial infection of as few as 50 oocysts will provoke a solid immunity to reinfection with the same species, and oocyst production ceases after about 10 days. Under field conditions, lambs are probably continually ingesting oocysts from pastures that become increasingly

contaminated as the season progresses. Thus, immunity to a range of species of coccidia is boosted by frequent reinfection.[40]

Very young lambs are relatively resistant to infection with a mixture of pathogenic species of coccidia, but susceptibility increases progressively up to at least 4 weeks of age.[2] Lambs inoculated at 4–6 weeks of age, develop severe diarrhea, whereas the same inoculum given at 1 day of age causes no clinical disease. Early subclinical infection improves the resistance of lambs to later challenge. When lambs receive a relatively heavy inoculation of oocysts during their first week of life they are relatively resistant to the pathogenic effects of some coccidia, are able to respond immunologically, and are protected from subsequent challenges.[2] This suggests that a challenge with coccidia, before the lamb becomes susceptible to their pathogenic effects, may help to reduce the incidence and severity of clinical coccidiosis later. Resistance to *E. zuernii* infection in calves occurs after chemotherapy, or experimental infection, with monensin or amprolium. Both drugs suppress the development of the experimental disease, during which time immunity develops. An effective immunity develops in piglets following natural or experimental infection with *I. suis*, which is the most immunogenic species of swine coccidium. Susceptible piglets are exposed to this species of infection in older swine. Piglets develop a more severe clinical disease when infected with *I. suis* at 1–3 days of age than when infected at 2 weeks of age.

26.2.3.12

Economic importance

Coccidiosis is sufficiently important economically in calves to warrant control measures. One estimate suggests that the economic losses from coccidiosis in calves amounts to US $1.00 per animal less than 1 year of age annually.

26.2.4

PATHOGENESIS

The coccidia of domestic animals pass through all stages of their life cycle in the alimentary mucosa and do not invade other organs, although schizonts have been found in the mesenteric lymph nodes of sheep and goats. The different species of coccidia localize in different parts of the intestine. *E. zuernii* and *E. bovis* occur primarily in the cecum, colon and the distal ileum, whereas *E. ellipsoidalis* and *E. arloingi* affect the small intestine. *E. gilruthi* localizes in the abomasum and occasionally the duodenum.[41]

26.2.4.1

Life cycle

The coccidial life cycle is self-limiting. The unsporulated oocysts are passed in the feces and develop into the infective stage in the environment. The original single cell divides, forming four sporoblasts, each of which develops into one sporocyst, and within each sporocyst two sporozoites develop. When ingested, the wall of the oocyst breaks down and the sporocysts are released. The sporocysts then enter epithelial cells. Once within the cells the sporozoites undergo asexual multiple fission (schizogony) and become **first-generation shizonts**, which form numerous merozoites. After the schizont matures, the merozoites are released by rupture of the epithelial cell. New epithelial cells are again invaded and **second-generation schizogony** occurs in the large intestine. This is followed by the release of another generation of merozoites, which invade epithelial cells and produce the sexual stages, **the macrogametocyte and the microgametocyte**. The second-generation schizogony and fertilization of the macrogametocyte by the microgametocyte (**gametogony**) are the stages of the life cycle that cause functional and structural lesions of the large intestine. As the second-generation schizonts or gamonts mature, the cells containing them slough from the basement membrane and cause hemorrhage and destruction of the cecum and colon. The oocysts are the result of fertilization of the gametocytes and are discharged at the time of rupture of the cells, which usually coincides with the onset of clinical signs of dysentery. The prepatent period varies with the species of coccidia; with *E. bovis* it is 5–20 days, and with *E. zuernii* 15–17 days. Oocyst production in calves infected with *E. zuernii* reaches peak numbers on the 19th and 20th day after experimental infection. The prepatent period of *E. alabamensis* varies from 6 to 8 days.

E zuernii and *E. bovis* are most pathogenic to **cattle** and their life cycles are similar. In calves infected with *E. zuernii*, first-generation schizogony occurs in the lower ileum, and second generation schizogony and gametogony occurs in the cecum and proximal colon. The gametocytes are the pathogenic stages and cause rupture of the cells they invade, with consequent exfoliation of the epithelial lining of the intestine. It is notable that the oocyst count is often low when the disease is at its peak, as the oocysts have not yet formed. Exfoliation of the mucosa causes diarrhea, and in severe cases, hemorrhage into the intestinal lumen, and the resulting hemorrhagic anemia may be fatal. If the animal survives this stage, the life cycle of the coccidia terminates without further damage and the intestinal mucosa will regenerate and return to normal. The patent period for *E. bovis* and *E. zuernii* varies from 5 to 12 days depending on the infecting dose of oocysts.

Treatment of calves with a corticosteroid can convert subclinical infection in calves into a peracute clinical form of the disease, which suggests that environmental, nutritional, and management factors may also act as stressors in producing clinical disease. The pathophysiological changes associated with experimental infection of calves with *E. zuernii* include a decrease in packed cell volume and reduction in plasma sodium and chloride levels. However, these are not remarkable; in naturally occurring cases the changes are not significant.

In **lambs**, most natural infections are composed of several different species of coccidia and there is a wide range of values in the production of oocysts from individual lambs, either in the feces from the same lamb over a period of time or in the feces from a number of lambs on any one occasion. Under practical conditions, constant reinfection occurs and waves of pathogenic stages succeed each other. The occurrence of villous atrophy in the intestinal mucosa of lambs affected by coccidiosis is probably related to the recurrence of diarrhea and loss of body weight.

However, in lambs at least, there is some doubt about the effects of coccidial infection on growth rate, feed consumption, and clinical signs in the experimental disease. There may be no obvious relationship between infective dose, the fecal oocyst production, and clinical disease. This suggests that, in lambs, the mere presence of large numbers of fecal oocysts does not constitute a diagnosis of coccidiosis and that other pathogenetic factors may be involved in conversion to clinical disease. It is also possible that the large number of oocysts may represent non-pathogenic coccidia.

Severely affected calves surviving the acute phase of the disease do not regain losses in body weight unless they are fed for an additional 3–4 weeks, suggesting that bovine coccidia can have a marked effect on performance. A subclinical coccidial infection superimposed on an established, low-grade, subclinical nematode infection in the small intestine may have a marked effect on the mineralization of the skeletal matrix in young adult ruminants, predisposing these animals to osteodystrophy.

The fact that multiple infections are so common may explain the variations in oocyst discharge from infected animals, but more importantly in groups of animals. New cases may develop every few days for a few weeks because of the variations in the length of the prepatent period between species of coccidia.

The **pathogenesis of the nervous signs of coccidiosis** in calves is unknown. Detailed examination of a series of cases excluded possible explanations such as:

- Alterations in serum electrolytes
- Vitamin A and thiamin deficiencies
- Lead poisoning
- Uremia, *Haemophilus somnus* meningoencephalitis
- Severity of clinical disease
- Gross alteration in intestinal bacterial flora and hepatopathy.[7]

A labile neurotoxin in the serum of calves with 'nervous coccidiosis' has been identified using laboratory mice as test subjects, but its significance is unknown.[7]

The **pathogenesis of bovine winter coccidiosis**, which occurs during or following very cold weather in Canada and the northern United States, is not understood. In January, February, and March, the outside temperatures may reach – 40°C (–40°F) with daily mean temperatures of – 10 to – 15°C (14–5°F) for several days consecutively. Such temperatures should be too cold for sporulation of oocysts in feces on the ground. There is speculation that sporulation could occur on the moist hair coats of cattle, or the endogenous stages of *E. zuernii* may be in a latent phase and reactivated by the stress of cold weather.

Isospora suis has at least three asexual, and one sexual, intra-intestinal multiplication cycles. All stages are most prominent in the distal half of the small intestine, but also occur in the proximal small intestine, cecum and spiral colon. The prepatent period extends from 8 to 16 days and the shedding of oocysts occurs in a cyclic pattern, with 2–3 peaks separated by intervals of about 5 days.[35] This biphasic disease course results in diarrhea, villous atrophy and necrosis of intestinal epithelium at 4–6 and 8–10 days after infection. **The feces may also be negative for oocysts between the biphasic peaks**. Under temperature ranges of 32–35°C (89.5–95°F) the oocysts of *I. suis* can sporulate and become infective within 12–16 hours. An extra-intestinal stage of the life cycle related to the second patent period is postulated. The lesions are most pronounced in the small intestine, and consist of villous atrophy and focal ulceration from the destruction of villous epithelial cells, principally during the peak of asexual reproduction. A fibrinonecrotic pseudomembrane may develop in severe cases. A combined experimental infection of *I. suis* and rotavirus in gnotobiotic and conventional pigs results in a synergistic action based on a competition of rotavirus and the coccidia for mature, enzymatically active absorptive

1502
1503

villous cells.[42] The effects of neonatal *I. suis* infection on protein dynamics may persist after clinical recovery and could contribute to suboptimal weight gains.

26.2.4.1.1 Experimental reproduction.

The effects of experimental *Eimeria bovis* infection on the metabolism of water, sodium, and potassium in calves has been examined.[43] Although acute sublethal bovine coccidiosis alters electrolyte and water metabolism, the overall balance of electrolytes and water is largely maintained by physiologic adaptation. This supports field observations that most cases of clinical coccidiosis do not require supportive fluid and electrolyte therapy.

Piglets experimentally inoculated with *I. suis* at 3 days of age develop a strong level of resistance to reinfection. Piglets develop more severe clinical signs of coccidiosis when inoculated with *I. suis* at 3 days of age than at 19 days of age. This suggests that maturation of non-specific components of the immune system is more important in the resistance of neonatal piglets to *I. suis* infection than specific immune mechanisms.[44]

26.2.5 CLINICAL FINDINGS

The incubation period after experimental dosing varies between species of coccidia and animals infected. It ranges from 16 to 30 days in cattle infected with *E. zuernii* and *E. bovis*, from 14 to 18 days in sheep, and as short as 5 days in piglets. The clinical syndromes associated with the various coccidia are similar in all animal species.

26.2.5.1 Cattle and sheep

A mild fever may occur in the early stages, but in most clinical cases the temperature is normal or subnormal. The first sign of clinical coccidiosis is the sudden onset of diarrhea with foul-smelling, fluid feces containing mucus and blood. Blood may appear as a dark, tarry staining of the feces or as streaks or clots, or the evacuation may consist entirely of large clots of fresh, red blood. The perineum and tail are commonly smudged with blood-stained feces. Severe straining is characteristic, often accompanied by the passage of feces, and rectal prolapse may occur. The degree of hemorrhagic anemia is variable depending on the amount of blood lost, and in most naturally acquired cases in calves anemia is not a feature. In experimental cases of coccidiosis in lambs, due to *E. ninakohlyakimovae*, although 50% of the animals died, there was no evidence of blood loss, but there was

significant hemoconcentration. However, in exceptional cases, anemia is severe with pale mucosa, weakness, staggering, and dyspnea. Dehydration is common, but is not usually severe if affected animals continue to drink water.

Inappetence is common and in exceptional cases there may be anorexia. The course of the disease is usually 5–6 days, but some animals undergo a long convalescent period during which feed consumption and body weight gains are subnormal. Severely affected calves do not quickly regain the body weight losses which occurred during the clinical phase of the disease. In mild cases there is diarrhea and reduced growth rate, but not necessarily dysentery too. Subclinical cases show inferior growth rate and chronic anemia only.

Clinical coccidiosis occurs only rarely in adult cattle, and the few reports describe several animals affected over a short period of time.[45] Young dairy cows may be affected commonly within 6–8 weeks after calving. Diarrhea, dysentery, tenesmus, pale mucous membrane, thickening and corrugation of the rectal wall, and rapid recovery often without treatment are common.

26.2.5.2

Coccidiosis with nervous signs

Nervous signs consisting of muscular tremors, hyperesthesia, clonic–tonic convulsions with ventroflexion of the head and neck and nystagmus, and high mortality rate (80–90%) occurs in calves with acute clinical coccidiosis.[7] Outbreaks of this ‘nervous form’ have occurred in which 30–50% of all susceptible calves are affected. It has occurred most commonly during, or following, severely cold weather in midwinter in Canada and the northern United States. Affected calves may die within 24 hours after the onset of dysentery and the nervous signs, or they may live for several days, commonly in a laterally recumbent position with a mild degree of opisthotonos. In spite of intensive supportive therapy, the mortality is high. Nervous signs have not been reported in experimental clinical coccidiosis in calves, which suggests that the nervous signs may be unrelated to the dysentery or, indeed, even to coccidiosis.

26.2.5.3

Lambs

Coccidiosis in lambs is generally similar to that in calves, but with much less dysentery. In groups of lambs raised and fed under intensified conditions, inferior growth rate, diarrhea with or without blood, low-grade abdominal pain, gradual onset of weakness, inappetence, fleece damage, mild fever, recumbency, emaciation, and death with a course of 1–3 weeks were noted. The diarrhea may escape cursory examination of the animals, but clinical

examination of affected lambs reveals a perineum smudged with feces, and soft feces in the rectum. Lambs moved directly from range pasture to a feedlot with little or no previous exposure to coccidia often develop acute disease with a high morbidity and case fatality rate.

26.2.5.4 Horses

In the horse, while there is some doubt about the pathogenicity of *E. leuckarti*, diarrhea of several days duration, and acute massive intestinal hemorrhage leading to rapid death have been described in foals and young horses.[4]

26.2.5.5 Piglets

In piglets, severe outbreaks of coccidiosis occur between 5 and 15 days of age.[42] Anorexia and depression are common. There is profuse diarrhea and the feces are yellow, watery, and sometimes appear foamy. The diarrhea may persist for several days when dehydration and unthriftiness are obvious. Although affected piglets continue to suck, they become dehydrated and lose weight. Vomition may occur. Entire litters may be affected, and the case fatality rate may reach 20%. The disease may persist in a herd for several weeks or months, particularly where a continuous farrowing program is used.

26.2.6 CLINICAL PATHOLOGY

26.2.6.1 Oocyst count

A count of over 5000 oocysts/g of feces of ruminants is considered significant. Although counts below 5000/g of feces do not usually suggest clinical disease, they may indicate a potential source of severe infection if environmental conditions for spread become favorable. Oocyst counts of over 100 000/g are common in severe outbreaks, although similar counts may also be encountered in normal sheep. The output of oocysts following an acute infection falls sharply after the peak, which may result in a critically affected animal with dysentery and low oocyst count. If oocysts are not found and the disease is suspected, merozoites can be looked for in direct smears; they do not float on the conventional concentrated sugar or salt solutions used for flotation of oocysts. The several species of coccidia can be differentiated, up to a point, by the characteristics of the oocysts.

26.2.6.2

Calves

Affected animals exposed to a large number of oocysts may develop severe dysentery a few days before oocysts appear in the feces. However, this is not commonly observed when the feces from several affected animals are examined, and usually within 2–4 days after the onset of dysentery the oocysts will appear in the feces. The period during which oocysts are discharged in significant numbers (patent period) will vary between species of coccidia, the age of the animal, and the degree of immunity, which often makes it necessary to examine a number of animals in a group or herd rather than rely on the results from a single animal.

1503 1504

26.2.6.3

Lambs

In lambs at pasture, oocysts first appear in the feces at about 2 weeks of age. The oocyst count continues to rise in the lambs until about 8–12 weeks when the counts will be 10^5–10^6/g of feces. Thereafter, the count declines to about 500/g when the lambs are 6–12 months of age. There is also considerable variation, both between lambs and in day-to-day samples from individuals, in the numbers and species of oocysts present in the feces. Hence the need for examination of several samples over a period of several days to assess the burden.

26.2.6.4

Piglets

In piglets, the prepatent period varies from 4 to 7 days (most commonly 5 days) and oocysts are shed in the feces for 5–8 days after the onset of clinical signs. Piglets may develop the disease at 5 days of age, and oocysts may not be present in the feces until 3 days later. The use of a saturated sodium chloride with glucose as a flotation solution is recommended when examining piglet feces for *I. suis*.[46]

Necropsy examination of selected untreated clinical cases is often necessary to make the diagnosis. The disease should be suspected when piglets 5–8 days of age develop a diarrhea that responds poorly to treatment. Outbreaks of diarrhea in piglets under 5 days of age are usually associated with *Escherichia coli* or transmissible gastroenteritis. However, mixed infections are common and extensive laboratory investigations are often necessary to isolate the causative agents. The diagnosis often requires a combination of consideration of the history of diarrhea in piglets 5–15 days of age, gross and microscopic lesions, the presence of coccidial stages in mucosal smears and histological sections, and identification

of oocysts in intestinal contents and feces. In heavy infections, piglets may die before the sexual stages of the parasite develop and the diagnosis is dependent upon finding lesions, schizonts, and merozoites of *I. suis* in the middle jejunum and ileum. The developmental stages can be detected by the mucosal smear technique. A rapid field diagnostic procedure consists of staining glass slide impression smears of the mucosa of the ileum and jejunum.

26.2.6.4.1

Autofluorescence microscopy.

This technique is superior to bright field microscopy in detecting *I. suis* oocysts after flotation and is significantly more sensitive when direct smears are examined.[47] It does not require purification of samples and requires no agents to prepare them. The calculated detection limit of autofluorescence is 10 oocysts per gram (using 100 mg of feces per smear); the flotation technique provides a lower detection rate of 334 oocysts per gram of feces.

26.2.6.4.2

PCR detection.

The PCR test is the most sensitive technique for the detection of *I. suis* and can be used when large numbers of samples are examined, and in experimental situations.[48] The PCR can also be used to differentiate *Eimeria polita*, *Eimeria porci*, and *Eimeria scabra* from *I. suis*.[49]

26.2.7

NECROPSY FINDINGS

Carcasses often have generalized tissue pallor and there is usually fecal staining of the hindquarters. **In cattle**, congestion, hemorrhage, and thickening of the mucosa of the cecum, colon, rectum, and ileum are the characteristic gross changes at necropsy. The thickening may be severe enough to produce ridges in the mucosa. Small, white cyst-like bodies, formed by large schizonts, may be visible on the tips of the villi of the terminal ileum. Ulceration or sloughing of the mucosa may occur in severe cases. The lesions associated with experimental *E. bovis* infection in the small and large intestines are characterized by a fibrinous typhlitis and colitis. Clotted blood or bloodstained feces may be present in the lumen of the large intestine. Histologically, there is denudation of the epithelium, and merozoites may be observed in some cells. Smears of the mucosa or intestinal contents should be examined for the various developmental stages.

The necropsy findings **in sheep** are marked by more severe involvement of the small intestine than in cattle. Atrophy of the villi in the proximal ileum occurs in both natural and

experimental infection in lambs. In experimental *E. crandallis* infection in lambs, there is loss of surface epithelial cells, atrophy of villi in the small intestine, and severe diffuse crypt hyperplasia in the small and large intestines.[41] *E. ovinoidalis* infection in lambs causes massive invasion of the cecum, with destruction of crypt stem cells leading to denudation of the cecal mucosa. In naturally acquired coccidiosis of lambs, three types of macroscopic intestinal lesions may be recognized:

1. Flat oocyst patches, which are whitish spots 1–2 mm in diameter
2. Raised oocyst patches on enlarged villi
3. Polyps which are proliferative lesions protruding into the lumen.

All three lesions contain heavy concentrations of gamonts and oocysts. In sheep affected with *E. gilruthi*, the abomasum contains numerous nodules, 1–2 mm in diameter, similar in gross appearance to ostertagiasis. These nodules contain the large schizonts of *E. gilruthi*-containing merozoites.[3]

In piglets, the small intestines are usually flaccid, but occasionally a fibrinonecrotic enteritis may be noted. Clinical signs precede the production of oocysts, so mucosal scrapings should be examined for the presence of earlier stages of the life cycle.

26.2.7.1

Samples for confirmation of diagnosis

- **Parasitology** – feces (FECAL); segments of jejunum, ileum, colon (DIRECT SMEAR)
- **Histology** – formalin-fixed duodenum, jejunum, ileum, cecum, colon (LM).

26.2.7.1.1

DIFFERENTIAL DIAGNOSIS

26.2.7.1.1.1

Calves

In calves, clinical coccidiosis is characterized by dysentery, tenesmus, mild systemic involvement and dehydration. The presence of large numbers of oocysts supports the diagnosis, and necropsy findings are usually characteristic. When nervous signs occur in calves appearing to have coccidiosis, differentiation from other diseases causing brain dysfunction must be made.

26.2.7.1.1.2

Sheep

In sheep, the diagnosis is dependent on the clinical findings of diarrhea and dysentery, the presence of large numbers of oocysts in the feces, and the intestinal lesions at necropsy. Large numbers (100 000/g) of oocysts may occur in the feces of normal lambs, and thus the observation of large numbers of oocysts in the feces of lambs affected with diarrhea and/or dysentery may not, in itself, constitute a diagnosis of coccidiosis. In lambs that have had previous contact with coccidia, and that may be relatively immune, other causes of diarrhea such as helminthiasis, salmonellosis, *Clostridium perfringens* type C enterotoxemia, and helminthiasis should be considered. See Table 26.3 for epidemiological and clinical features of the diseases causing diarrhea in sheep and goats.

26.2.7.1.1.3

Piglets

In piglets, diarrhea due to coccidiosis must be differentiated from enteric colibacillosis, transmissible gastroenteritis, rotavirus infection, *Strongyloides ransomi*, and *Clostridium perfringens* type C. See Table 26.3 for epidemiological and clinical features of the diseases causing diarrhea in pigs.

26.2.7.1.1.4

Foals

See Table 26.3 for the epidemiological and clinical features of the diseases causing diarrhea in foals. The common causes of diarrhea of foals include those associated with: *Salmonella* spp., *Actinobacillus equuli*, and rotaviruses.

1504

1505

26.2.8

TREATMENT

Coccidiosis is a self-limiting disease, and spontaneous recovery without specific treatment occurs commonly when the multiplication stage of the coccidia has passed. Many treatments have been recommended without taking this into account and it is unlikely that any of the chemotherapeutic agents in common use for clinical coccidiosis has any effect on the late stages of the coccidia. Most of the coccidiostats have a depressant effect on the early, first-stage schizonts and are used for control.

In an outbreak, the clinically affected animals should be isolated, and given supportive oral and parenteral fluid therapy as necessary. The population density of the affected pens should be reduced. All feed and water supplies should be high enough off the ground to avoid fecal

contamination. Mass medication of the feed and water supplies may be indicated in an attempt to prevent new cases and to minimize the effects of an epidemic. Cattle with coccidiosis and nervous signs should be brought indoors, kept well-bedded and warm, and given fluid therapy orally and parenterally. However, the case fatality is high in spite of intensive supportive therapy. Sulfonamide therapy parenterally may be indicated to control the development of secondary bacterial enteritis or pneumonia, which may occur in calves with coccidiosis during very cold weather. Corticosteroids are contraindicated.[8]

26.2.8.1

Calves and lambs.

The chemotherapeutic agents recommended for treatment and control of coccidiosis in calves and lambs are summarized in Table 26.4. There is insufficient information available to make reliable recommendations for the specific treatment of acute clinical coccidiosis. None of these chemotherapeutic agents has been adequately tested in clinical trials. Sulfadimidine is used widely empirically for the treatment of acute clinical coccidiosis in calves. **Amprolium** is also used for treatment, and there may be a beneficial effect in terms of increased body weight gains and feed consumption compared to untreated controls recovering spontaneously.

Table 26.4 Chemotherapeutics recommended for treatment and control of coccidiosis in calves and lambs

Chemotherapeutic agent	Treatment	Prevention
Sulfadimidine (sulfamethazine)	*Calves and lambs:* 140 mg/kg BW orally daily for 3 days individually	*Calves*: in feed 35 mg/kg BW for 15 days *Lambs*: daily dose 25 mg/kg BW for 1 week
Amprolium	*Calves*: individual dose at 10 mg/kg BW daily for 5 days or 65 mg/kg BW one dose	*Calves*: in feed at 5 mg/kg BW for 21 days *Lambs*: in feed, 50 mg/kg BW for 21 days
Monensin	*Lambs*: 2 mg/kg BW daily for 20 days beginning on 13th day following experimental inoculation	Lambs: 20 mg/kg feed fed continuously *Calves*: 16.5 or 33 g/tonne for 31 days
Lasalocid		*Lambs*: 25–100 mg/kg feed from weaning until market. Also, in ewe's diet from 2 weeks before and until 60 days after lambing.

26.2.8.2

Piglets.

Symmetrical triazintriones are effective against the asexual and sexual stages of experimental *I. suis* infection in piglets and is most effective before the onset of clinical signs.[50]

26.2.9

CONTROL

The control of coccidiosis assumes greatest importance in calves and lambs, and has been difficult to achieve with reliability.

26.2.9.1

Management of environment

Successful economical control will depend on avoiding the overcrowding of animals while they develop an immunity to the coccidial species in the environment. Only small numbers

(50/day) of oocysts are required for the development of solid immunity in lambs. Lambing and calving grounds should be well drained and kept as dry as possible. Lambing pens should be kept dry, cleaned out frequently, and bedding disposed of so that oocysts do not have time to sporulate and become infective.[51] All measures that minimize the amount of fecal contamination of hair coats and fleece should be practiced regularly. Feed and water troughs should be high enough to avoid heavy fecal contamination. Feeding cattle on the ground should be avoided if possible, particularly when overcrowding is a problem.

26.2.9.2

Lambs at pasture

In groups of lambs at pasture, the frequent rotation of pastures for parasite control will also assist in the controls of coccidial infection. However, when lambs are exposed to infection early in life as a result of infection from the ewe and a contaminated lambing ground, a solid immunity usually develops and only when the stocking density is extremely high will a problem develop.

26.2.9.3

Feedlot cattle and lambs

Control of coccidiosis in feeder calves and lambs brought into a crowded feedlot depends on management of population density, or use of chemotherapeutics, to control the numbers of oocysts ingested by the animals while effective immunity develops. Management procedures include establishing the optimum stocking density, which can be assessed by visual inspection. When animals are overcrowded they usually become dirty, there is excessive competition for feed supplies, and growth rate may be affected.

26.2.9.4

Piglets

The control of coccidiosis in newborn piglets infected with *I. suis* has been unreliable. The use of coccidiostats in the feed of the sow for several days or a few weeks prior to, and following, farrowing has been recommended and used in the field, but the results are variable. Amprolium and monensin have been evaluated for the prevention of experimental coccidiosis in piglets and are ineffective. A control program designed to decrease the number of oocysts has been recommended and consists of proper cleaning, disinfection, and steam cleaning of the farrowing housing. Amprolium (25% feed grade) at the rate of 10 kg/tonne of sows' feed beginning 1 week before farrowing and continued until the piglets are 3 weeks of age has been recommended, but the results are unsatisfactory. A single oral dose of 1.0 mL of toltrazuril given to piglets 3–6 days of age reduced the

occurrence of coccidiosis from 71% to 22%, and the number of days that oocysts were excreted in the feces reduced from 4.9 to 2.5.[52]

A single treatment of toltrazuril at 20 mg/kg BW at an early stage of infection (2 days post-infection) controlled a large experimental infection with *I. suis* in suckling pigs.[53]

26.2.9.5

Coccidiostats

Coccidiostats are used for the control of naturally occurring coccidiosis in calves and lambs. The ideal coccidiostat suppresses the full development of the life cycle of the coccidia, allows immunity to develop, and does not interfere with production performance. Those that have been used for treatment and control are summarized in Table 26.4.[54]

To be effective, coccidiostats must be given beginning early in the life cycle of the coccidia. In any group of animals, there will be several different species of coccidia at different stages of the cycle: some at the drug-susceptible stage (before 13–15 days in calves) and some beyond the drug-susceptible stage (after 16–17 days), which explains why coccidiostats appear to be effective in some epidemics and ineffective in others. In an epidemic in calves, new cases may develop for up to 12–15 days after the commencement of feeding of an effective coccidiostat to in-contact calves. However, the stage of the prepatent period is unknown at any particular point in time in the affected group, and the most that can be done is to medicate the feed and water supplies with the coccidiostat of choice, treat new cases that develop, and avoid the stressors of overcrowding and nutritional disorders.

1505 1506

Some comments about some of the coccidiostats are made here. Routine prophylactic medication of the feed and water supplies of feeder calves and lambs with an effective coccidiostat will usually control the disease and allow the development of effective immunity.

26.2.9.6

Antimicrobials

Sulfonamides in the feed at a level of 25–35 mg/kg BW for at least 15 days are effective for the control of coccidiosis in calves and lambs. Sulfadimidine at 55 g/tonne is also effective in goats. A combination of chlortetracycline and a sulfonamide has provided protection in calves and lambs

26.2.9.7

Ionophores

Monensin is an effective coccidiostat and growth promotant in cattle, sheep, and goats. The recommended levels are 16–33 g/tonne feed for calves and 20 g/tonne of feed for lambs. Levels of 11 g/tonne feed are not as reliable as the higher dose for calves. The recommended level for goats is 16 g/tonne of feed. A concentrated ration containing monensin at 15 g/tonne can be fed to ewes from 4 weeks before lambing until weaning, and to lambs from 4 to 20 weeks of age. Monensin can markedly reduce the oocyst output of ewes and lambs when fed before and after lambing. Withdrawal of the monensin may be followed by the development of fatal coccidiosis in some animals, presumably because the drug suppressed the development of immunity. Postweaning coccidiosis in beef calves has been controlled using monensin from intraluminal continuous release devices. The toxic level of monensin for lambs is 4 mg/kg BW.

Lasalocid is related to monensin and is also an effective coccidiostat for ruminants. For maximum benefit, lasalocid should be used daily in the feed of coccidia-susceptible lambs for as long as possible. An effective method of control is to medicate the feed of the ewes beginning about 2 weeks before lambing and continue the medication until the lambs are weaned. The lambs begin to receive lasalocid in their creep ration, and later in their rations from weaning until market. For maximum control of coccidiosis and improved feedlot performance, lasalocid should be given before and during the time that coccidia-naive lambs are first exposed to the natural occurrence of oocysts. A level as low as 25 mg/kg of feed will control coccidiosis and improve performance when fed to lambs in early life. Similar improvements in feedlot performance do not occur in heavier lambs already passing oocysts and being fed lasalocid at 25 mg/kg feed.

Lasalocid fed at a rate of 40 mg/kg of starter to dairy calves beginning at 3 days of age, and up until 12 weeks of age, is effective in reducing fecal oocysts and increasing mean daily body weight gain, dry-matter intake, and improved feed efficiency.[55] Mixing lasalocid in the milk replacer of calves beginning at 2–4 days of age is an effective method of controlling coccidiosis.[56] It is also effective as a coccidiostat when fed free-choice in salt at a level of 0.75% of the total salt mixture. Lasalocid at levels from 0.75 to 3 mg/kg BW are effective in preventing experimental coccidiosis in calves. The level of 1 mg/kg BW is the most effective and rapid, and is recommended when outbreaks of coccidiosis are imminent in cattle. Lasalocid and decoquinate are effective in reducing coccidia infections in young calves under conditions of apparent low exposure and good management.

However, neither lasolocid nor decoquinate, or both, added to the feed of 16-week-old dairy calves naturally infected with subclinical coccidiosis for 56 days had any significant effect on weight performance.[57]

Monensin, lasalocid and decoquinate at the manufacturer's recommended levels are equally effective. A combination of monensin and lasalocid at 22 and 100 mg/kg of diet, respectively, is an effective prophylactic against naturally occurring coccidiosis in early weaned lambs under feedlot conditions. The ionophores are used in the feed continuously from weaning to market, and provide control of coccidiosis and improve feedlot performance. The continuous feeding of lasalocid, decoquinate or monensin will effectively control coccidiosis; cessation of medication may result in the appearance of oocysts in the feces and diarrhea.

Decoquinate in the feed at 0.5–1.0 mg/kg BW suppressed oocyst production in experimentally induced coccidiosis of calves.[58] It is most effective in preventing coccidial infections when fed continuously in dry feed at 0.5 mg/kg BW.[59] When fed to dairy calves from 9 weeks to 24 weeks of age, there was an improvement in growth rate, height at withers, and heart girth measurement.[10] A level of 0.5 mg/kg BW is effective in goats.

Toltrazuril at 20 mg/kg BW as a single dose, 10 days after being turned out to pasture, will almost completely prevent coccidiosis, which occurred commonly without prophylactic medication. A dose of 15 mg/kg BW is effective to control experimental infections of calves with *E. bovis*.[60] In addition, medication of naturally infected lambs with toltrazuril on day 10 after turnout will markedly reduce the excretion of oocysts for a prolonged period, and thus lessen the contamination of the pasture with oocysts. A single treatment of toltrazuril can significantly reduce the oocyst output in naturally infected lambs for a period of approximately 3 weeks after administration. Weekly oral treatment of suckling lambs with 20 mg/kg BW of toltazuril reduced the oocyst output and improved weight gain over a 10-week period.[61]

26.2.9.8

Vaccines

The literature on the prospects for subunit vaccines against protozoa of veterinary importance has been reviewed.[62] Although subunit vaccines offer many theoretical advantages, the lack of understanding of immune mechanisms to primary and secondary infection and the capacity of many protozoa to evade the host immunity remain obstacles to developing effective vaccines.

1507

26.3 SARCOCYSTOSIS (SARCOSPORIDIOSIS)

26.3.1 Synopsis

26.3.1.1 Etiology

Sarcocystis species. There are a number of species, with a number of different carnivore species as their final host but generally a specific intermediate host.

26.3.1.2 Epidemiology

High prevalence of infection in most areas. Source of infection is feces of carnivore, primarily farm dogs and cats fed raw meat, or other carnivores if they have access to ruminant carcasses.

26.3.1.3

Clinical findings

Severity of disease dose-dependent. The vast majority of infections are sub-clinical. Abortion, depressed growth rate. Neurological disease and ataxia in sheep. Severe infection with some species results in carcass condemnation.

26.3.1.4

Clinical pathology

Anemia and elevated blood concentrations of enzymes associated with tissue damage in acute disease.

26.3.1.5

Lesions

Non-suppurative encephalitis in sheep with neurological signs. Non-suppurative encephalitis, myocarditis, and hepatitis in aborted fetus. Cysts in carcass in chronic cases.

26.3.1.6

Diagnostic confirmation

Identification of parasite microscopically in biopsy or postmortem material.

26.3.1.7

Treatment and control

No effective treatment, amprolium or salinomycin may aid in control. Proper disposal of carcasses. Raw meat not to be fed to farm dogs and cats. Coyote control.

26.3.2

ETIOLOGY

Sarcocystis species are obligate two-host sporozoan parasites in the phylum Apicomplexa. There are a number of species, each with definitive omnivorous or carnivorous species as final hosts. One system of naming the species identifies the intermediate and definitive host in the name, i.e. *S. bovifelis*, and has been commonly used in the literature. However, currently the organisms are identified by their original names. Table 26.5 shows the currently accepted name of *Sarcocystis* species of importance in agricultural animals and their definitive hosts.

26.3.3 EPIDEMIOLOGY

26.3.3.1 Occurrence

In all countries where there have been surveys, the prevalence of infection in cattle, sheep, and horses approaches 100% with a lower, but significant infection rate in swine.[1] Clinical disease is rare.

26.3.3.2 Source of infection

Sarcocystis spp. have an obligatory prey – predator live-host life cycle in which the definitive host is a predator or scavenger.[1,2] The **carnivorous definitive host** becomes infected by ingesting tissue of the intermediate host that contains mature sarcocysts. Following ingestion, bradyzoites are released from the sarcocyst in the stomach and intestine, and they transform into micro- and macrogamonts. The male microgamonts mature to release microgametes, which fertilize the macrogamont to form an oocyst. The oocyst subsequently sporulates to release **sporocysts** which are passed in the feces and contain infective sporozoite.

Table 26.5 Definitive and intermediate hosts for *Sarcocystis* sp.-associated infections in agricultural animals

Intermediate host	*Sarcocystis* spp.	Synonyms	Definitive host
Cattle	*S. cruzi*	*S. bovicanis*	Dog, wolf, fox, raccoon, coyote
	S. hirsuta	*S. bovifelis*	Cat
	S. hominis	*S. bovihominis*	Humans
Sheep	*S. tenella*	*S. ovicanis*	Dog, coyote, fox
	S. arieticanis	–	Dog
	S. gigantica	*S. ovifelis*	Cat
	S. medusiformis	–	Cat
Goats	*S. capracanis*	–	Dog, coyote, fox
	S. hericanis	–	Dog
	S. moulei	–	Cat
Pigs	*S. miescheriana*	*S. suicanis*	Dog, raccoon, wolf
	S. suihominis	–	Human
	S. porcifelis	–	Cat
Horses	*S. bertrami*	*S. equicanis*	Dog
	–	*S. fayeri*	
	S. neurona	–	New world opossums

The prepatent period is variable, approximately 14 days, and there is no illness in the carnivore host in association with this cycle. However, the replicative cycle of the parasite in the intestine results in the presence of large numbers of sporocysts in the feces and the infection is **patent for a long period**. Intermediate hosts become infected by **ingesting sporocysts** in the food or water.[1,2]

26.3.3.3

Risk factors

26.3.3.3.1

Climate

Sporocysts are not dependent on weather conditions for maturation, and are quite resistant to environmental influences. Under experimental conditions they can survive

freezing, but they are susceptible to drying.[2] Consequently they can probably **overwinter** in the environment. Field studies have shown a lower herd prevalence of sarcocystosis in cattle in arid and semi-arid environments compared to cattle from temperate and tropical areas, which is probably a consequence of the relative aridity as well as the lower density of the definitive and intermediate hosts in arid areas.[3,4]

26.3.3.3.2

Species of Sarcocystis

Individual species vary in their **pathogenicity** and in their ability to produce clinical disease in the intermediate host. In cattle, for example, *S. cruzi* is considerably more pathogenic than *S. hominis*.[1,2]

1507

1508

S. tenella is the most pathogenic species for sheep, and *S. capricanis* for goats and naturally occurring clinical disease in sheep is not observed with *S. gigantea* or *S. medusiformis*.[5] There is a strong correlation between the number of sporocysts ingested and the severity of disease. The size of the sarcocyst that occurs in the tissues of the intermediate host also varies with the infecting species. Those from cats and occurring in sheep (*S. gigantea*, *S. medusiformis*) or cattle (*S. hirsuta*) are of particular economic importance, as they produce macroscopically visible sarcocysts that can result in meat condemnation. *S. cruzi* produces microscopic sarcocysts in muscle and will escape gross detection at meat inspection.

26.3.3.3.3

Farm dogs

There is a positive association between herds infected with *Sarcocystis* and the presence of working dogs on the farm, the practice of leaving carcasses in the field and the feeding of dogs with raw meat,[4] and virtually all of the reported clinical cases of sarcocystosis in cattle in the literature record that the dogs on the farm were fed offal or uncooked beef. Housing of dogs and cattle in the same shed or area can have increased risk for infection and clinical disease,[1,6] and cattle pastured close to farm buildings where there are dogs are at greater risk. The presence of foxes on farms is also strongly associated with *Sarcocystis* infection in those herds that leave carcasses on the field.[4]

26.3.3.3.4

Cats

The main risk for cat-associated sarcocystosis is the farm cat that is fed raw meat. Farm cats use hay barns as dens and can contaminate hay and other feedstuffs.[7] Feral cats have

the potential to distribute sporocysts widely in the grazing environment; however, the presence of feral cats on a farm may not increase the risk for *Sarcocystis* infection of cattle,[4] as scavenged sheep or cattle carcasses are a relatively unimportant part of the diet of feral cats.[7]

26.3.3.3.5 Stocking density

Risk for infection with *Sarcocystis* is higher with higher stocking densities,[4] which may reflect a more intense contamination of pastures by working dogs. Cattle on farms that graze sheep and cattle on the same pastures are less likely to be infected.

26.3.3.4 Economic importance

The major economic loss occurs with those sarcocysts that produce macroscopic cysts and meat condemnation. More severe infection depresses the growth rate, and there is a greater risk for abortion in infected herds.[4,8,9]

26.3.4 PATHOGENESIS

In the intermediate host, sporozoites are released from ingested sporocysts in the small intestine where they penetrate the mucosa and enter the endothelial cells of blood vessels. The stages of schizogony and the distribution of merozoites vary according to the species, but in cattle endothelial infection is followed by *parasitemia*, with merozoites subsequently localizing in striated muscle and nervous tissue where they develop into sarcocysts. Immature sarcocysts can be found in muscle 45–60 days following ingestion of sporocysts and are infective at about 70 days.[2]

Schizogony in the endothelial cells of the arterioles and capillaries results in **widespread hemorrhage** and anemia. Fever is associated with the parasitemia, and in the experimental disease coincides with the time of maturation of the first- and second-generation schizonts.[1] The *vascular lesion* appears to be an essential part of the disease's pathogenesis. It is proposed that the parasite produces growth retardation as a result of changes in plasma concentrations of somatostatin and growth hormone, and changes in cytokine interactions with the endocrine system.[10]

The severity of the illness and the degree of infection of tissues at postmortem examination in experimentally induced cases increase with the size of the **infective dose**. The number of

asymptomatic infections probably reflects the early ingestion of a few sporocysts that provoke a strong immunity to later challenge. When groups of animals that have not been exposed to infection previously are suddenly brought into contact with heavy contamination, especially from dogs and cats, outbreaks of clinical disease are likely to occur.

26.3.5 CLINICAL FINDINGS

Infection and disease can occur at all ages. Clinical disease may be more severe where there is **intercurrent nutritional stress**, and copper deficiency may be an exacerbating factor. Monensin is suspected of being able to potentiate recent infections to cause a severe myositis.[11]

26.3.5.1 Cattle

Acute illness is recorded with experimental infections but is rarely seen, or recognized, in the field. Illness commences with a rise in temperature and heart rate, followed by anorexia, anemia, weight loss, a fall in milk production, nervousness, muscle twitching, hypersalivation, lameness, abortion, and, in heavy infections, death. The agent is an occasional cause of non-suppurative encephalomyelitis in cattle and manifest with ataxia and recumbency.

Chronic disease in cattle is manifest by poor weight gains, loss of hair of the neck, rump and the switch of the tail (**'rat-tail'**), anemia, and abortion.

26.3.5.2 Sheep

In sheep, naturally occurring sarcocytosis has been associated with *S. tenella* and *S. arieticanis* and presents primarily as a **neurological disorder**, with muscle weakness, trembling, ataxia of varying severity, followed by hind limb paresis or flaccid paralysis and lateral recumbency. All ages of sheep can be affected, although lambs under 6 months are most susceptible. Attack rates in a susceptible group can be as high as 75% with a high case fatality rate.[12–16]

Infection may also be manifest with depressed growth, reduced wool growth, and anemia.[8,13] Less common manifestations include signs of congestive heart failure associated with endocardial and myocardial infection.[17] Infestation of the muscle of the esophagus in sheep is believed a cause of **esophageal dysfunction** and regurgitation in sheep.[18]

26.3.5.3

Swine

Natural clinical disease is not recognized. Sarcocystosis produced experimentally in pigs is manifested by cutaneous purpura on the snout, ears, and buttocks, and dyspnea, tremor and weakness or recumbency.[19] There is evidence that breed of pig affects the severity of clinical disease with experimental infections and also the subsequent severity of the parasite load.[20]

26.3.5.4

Abortion and perinatal fatality

Fetal infection, with abortion or neonatal mortality, is recorded in both cattle and sheep when pregnant animals are infected experimentally or naturally with pathogenic strains.[1,5,9,13]

26.3.6

CLINICAL PATHOLOGY

Characteristic laboratory findings in the systemic disease include a responsive anemia, a prolonged prothrombin time, and high titers of antibody to *Sarcocystis*. Blood creatine phosphokinase, lactic dehydrogenase, and aspartate aminotransferase are significantly elevated.[19] An indirect hemagglutination test (IHA) and an ELISA test are available for serological surveys. Titers of antibodies are not high at the time of an acute illness, but are at diagnostic levels 1 week to 3 months afterwards.[1,14] An ELISA based on antigens from merozoites has high sensitivity and specificity for detection of infection in individual animals, and a 100% sensitivity for detecting herd infection with small sample size.[21] Most animals have been exposed to *Sarcocystis* spp., and serological examination cannot differentiate clinical disease from asymptomatic infection.

26.3.7

NECROPSY FINDINGS

1508

1509

Emaciation, lymphadenopathy, laminitis, anemia and ascites are present, but the most obvious feature is the petechial and ecchymotic hemorrhages throughout the body.[22] There are also erosions and ulcerations in the oral cavity and esophagus, likely as a result of microvascular damage. Microscopically, schizonts are found in endothelial cells throughout the body, and hemorrhages, lymphocytic infiltration, and edema are seen in heart, brain, liver, lung, kidney, and striated muscle.[22] Death is probably a result of the severe necrotizing

myocarditis that occurs. There is an association between **eosinophilic myositis** and sarcosporidiosis, but this relationship is not proven in all cases.[1]

In sheep presenting with **neurological disease** there may be no findings at gross postmortem, but a non-suppurative encephalomyelitis on histological examination.[12,14,15] Aborted bovine fetuses show non-suppurative encephalitis, myocarditis, and hepatitis.[5]

A number of options are available to achieve a definitive diagnosis of the species present, including animal transmission studies, immunohistochemistry, electron microscopy and PCR. Such techniques are seldom required for routine diagnostic cases.

26.3.7.1

Samples for confirmation of diagnosis

- **Histology** – formalin-fixed heart, skeletal muscle (several sites, including tongue, masseter muscle) (LM).

26.3.7.1.1

DIFFERENTIAL DIAGNOSIS

Diagnosis in clinical cases is difficult because of the non-specific signs observed and the widespread prevalence of infection. Sarcosporidiosis is a consideration in the examination of problems of fever and anemia of undetermined origin in cattle and of ill-thrift in cattle and sheep.

Muscle biopsy may aid in the determination of the presence of infection, but still begs the question of its significance to the clinical disease.

The differential diagnoses for abortion in cattle are covered under brucellosis, and sheep under brucellosis. Causes of encephalitis and ataxia in sheep are listed under those headings.

26.3.8

TREATMENT

No approved treatment is available, but **amprolium or salinomycin** may relieve the signs. Amprolium 100 mg/kg given daily from the time of inoculation reduces the severity of infection in experimentally infected calves and sheep,[13,23] and has been used to control an outbreak in sheep.[12] Treatment of experimentally infected calves with salinomycin (4 mg/kg BW daily in divided doses for 30 days) reduced the severity of the illness.[24] Monensin may have a similar ameliorating effect,[9,25] but is also suspected of exacerbating muscle lesions.[10]

Oxytetracycline, at very high dose rates, and halofuginone may be effective in acute infections.[13]

26.3.9 CONTROL

Control is difficult as it involves the *separation of carnivores and stock*, which is not possible on most farms. However, infection in farm dogs and cats could be avoided if all meat fed to them was thoroughly cooked. Freezing will not destroy the infectivity. Coyotes and wild dogs should be controlled and livestock carcasses not left on fields. Prior exposure to small numbers of pathogenic sarcocysts produces a strong immunity, but there is no vaccine available.

26.4 NEOSPOROSIS

26.4.1 Synopsis

26.4.1.1 Etiology

The protozoan parasite *Neospora caninum*. The dog is identified as the definitive host for *N. caninum* but the major route of infection in cattle is by vertical transmission.

26.4.1.2 Epidemiology

An infection of cattle worldwide and associated with epidemic and endemic abortion. Point source and congenital infection occurs.

Clinical findings. Abortion in cows, perinatal mortality and encephalomyelitis in congenitally infected calves.

Clinical pathology. IFAT and ELISA serology on maternal serum and fetal fluids.

Necropsy findings. Fetal lesions of multifocal non-suppurative encephalitis, myocarditis, and periportal hepatitis. Infection confirmed by immunohistochemistry.

Diagnostic confirmation. A presumptive diagnosis can be based on the fetal histological lesions and seropositivity of the dam, but the definitive diagnosis requires the demonstration of the protozoa in fetal tissues by immunohistochemical labeling coupled with herd serological examinations.

Control. Feed hygiene and calving hygiene. Cull congenitally infected cattle.

26.4.2 ## ETIOLOGY

Neospora caninum, a protozoan parasite of the phylum Apicomplexa in the family Sarcocystidae. *N. caninum* primarily infects dogs and cattle but has a **wide host range** and infects all the major domestic livestock species, as well as companion animals and certain wildlife species. Dogs are the only known definitive host with cattle as the major intermediate agricultural animal host. Natural infections are infrequently reported in sheep, goats and deer.[1] *N. caninum* is a sporadic cause of encephalomyelitis and myocarditis in several species but its importance is its association with **endemic and epidemic abortion** in **cattle.** It is now the most common diagnosis for abortion in cattle in most countries. The organism can be isolated, with difficulty, from infected calves.[2]

26.4.3 ## EPIDEMIOLOGY

26.4.3.1 ### Occurrence

N. caninum was initially associated with abortion in the early 1990s in pastured cattle in Australia and New Zealand, and as a major cause of abortion in large dry-lot dairies in southern California, and dairies in New Mexico, Washington, and Arizona in the United States. Since then, abortion associated with *N. caninum* has been reported from many countries in cattle under varying management conditions, and has **worldwide occurrence**.

Abortion may be **epizootic or sporadic**. In epizootic abortion the number of cows aborting varies. It is usually between 5 and 10%, but up to 45% of cows may abort within a short period. The period of abortion may be a few weeks to a few months. There is no major seasonal occurrence and abortion occurs in both beef and dairy cows.[3,4] Sporadic abortions occur predominantly in cows that have been infected congenitally and seropositive cows

have greater risk for repeat abortions. Seropositivity in herds can be high, but varies widely. One study in dairy herds reports a within herd **seroprevalence** ranging from 7 to 70%[3] and another in beef herds a within-herd seroprevalence ranging from 6.5 to 67%.[5] Seropositive dams have a 3–7 fold higher risk of abortion than seronegative dams.[6,7]

26.4.3.2

Methods of transmission

There are two routes of infection of cattle. The dog is identified as the definitive host for *N. caninum* and infection of cattle can occur from the ingestion of oocytes in the dog feces contaminating feed or water. However vertical transmission occurs in both cattle and dogs and vertical (congenital) transmission appears the major route for infection in most cattle.[1,8]

Live-born calves from congenitally infected cows are themselves congenitally infected and the infection is believed to be **persistent and lifelong**. One study conducted on two dairies found 81% of seropositive cows gave birth to congenitally infected calves. Seroprevalence did not increase with cow age on either dairy, and was stable through the study period. The probability of a calf being congenitally infected was not associated with dam age, dam lactation number, dam history of abortion, calf gender, or length of gestation. Other studies have shown that this route of transmission is highly efficient resulting in infection of 50–95% of the progeny of seropositive dams.[9]

Congenital infection can result in abortion, or the birth of a normal, infected calf, and an infected cow can give birth to a normal, infected calf at one pregnancy and abort in the subsequent pregnancy.[3] The occurrence of infection in some herds can be associated with specific family lines.[10]

Whereas vertical transmission is the major route of infection that leads to sporadic abortions in cattle associated with *N. caninum* epidemiological evidence suggests that postnatal (point) infection is often the cause of outbreaks of abortion. Where dog feces are the source of infection many cattle are often exposed and this point source of infection commonly results in outbreaks of abortion. Farm dogs have been shown to have a higher seroprevalence to *N. caninum* than urban dogs suggesting that the disease cycles between cattle and dogs in rural environments.[11]

The importance of postnatal infection versus vertical infection in the genesis of abortion may vary between countries associated with differences in management systems.[12]

26.4.3.3

Experimental reproduction

Abortion has been produced by experimental challenge of fetuses and pregnant cattle with culture derived tachyzoites of *N. caninum*.[13] Fetal death and resorption or abortion has been reproduced in ewes challenged at 45, 65, and 90 days' gestation, but not 120 days, and lesions resemble those of ovine toxoplasmosis.[14] The disease has also been reproduced experimentally in goats,[15] but the importance and prevalence of this infection in naturally occurring abortions in small ruminants remains to be determined. Contaminated placenta, milk, and colostrum can result in infection of calves under one week of age.[16]

26.4.3.4

Risk factors

Outbreaks of abortion often appear to be point source infections, but the risk factors, other than probable mass exposure to infected dog feces, are not known. With suspect point source infection the disease in dairy herds frequently occurs as an epizootic, with multiple abortions occurring in a 1 to 2-month period. Severely autolytic fetuses are aborted in the 5th–7th month of pregnancy in most reports, but earlier abortions are recorded in some, and the agent has been associated with outbreaks where the gestational age of fetal loss has ranged from **3 to 8.5 months**.[3,6,17–20] Heifers may abort earlier in pregnancy than older cows.

Endemic abortion is more likely associated with the presence of **congenitally infected** cattle in the herd, which are at **high risk of aborting**, particularly in the initial pregnancy and in the pregnancy during the first lactation.[6,20] Cows that have aborted have higher risk for abortion in subsequent pregnancies, but the risk decreases with each subsequent pregnancy. The true frequency of repeat abortions is unknown because cows may be culled for abortion.

It has been postulated that immunosuppression resulting from concurrent infection with agents such as BVD virus may increase the risk for infection with *N. caninum* and precipitate outbreaks of abortion. Concurrent *N. caninum* and BVD infections in aborted fetuses have been observed in some studies and one study has found a significant association between abortion and cows with antibody to both *N. caninum* and BVD.[21] Others have found no association[22] and whereas concurrent BVD infection might be a risk factor in some outbreaks, it is not in all.

26.4.3.5

Economic importance

Economic loss is occasioned by the direct cost of abortions and the indirect costs associated with establishing the diagnosis and re-breeding or replacement costs. Seropositivity is also associated with increased risk of stillbirth and increased risk of retained placenta.

Seropositive heifers have been reported to produce less milk than seronegative herdmates.[1,3,23] However, this difference in milk production between seropositive and seronegative animals is not apparent in herds that are not experiencing an abortion problem.[24] In beef cattle seropositivity has been associated with reduction in average daily weight gain of 0.05 to 0.17 kg/head/day compared with seronegative cohorts and reduced food conversion efficiency rather than decreased food intake appeared the cause.[25] However, a subsequent study found no difference in production performance and carcass measures between seropositive and seronegative feedlot cattle.[26]

Estimates of economic loss associated with epidemic abortion include US$35 million/year in California, AUS$85/year to dairy and AUS$25 for beef cattle in Australia and NZ$17.8 for the dairy industry in New Zealand.[9]

26.4.4

PATHOGENESIS

The organism has a predilection for fetal chorionic epithelium and fetal placental blood vessels producing a fetal vasculitis and inflammation and degeneration of the chorioallantois, and widespread necrosis in the placentome.[14] Tachyzoites penetrate host cells and are located in a parasitophorous vacuole. They can be found in macrophages, monocytes, vascular endothelial cells, fibroblasts, hepatocytes, renal tubular cells, and in the brain of infected animals. With neuromuscular disease, cranial and spinal neural cells are infected. Cell death is by the active multiplication of tachyzooites.

26.4.5

CLINICAL FINDINGS

Abortion is the only clinical sign observed in infected **cows**. Fetuses may die in-utero, be reabsorbed, be mummified, stillborn, born alive but diseased, or born clinically normal but chronically infected. Cows that are infected have **decreased milk production** in the first lactation, producing approximately 1 liter less of milk/cow/day than uninfected cows, are prone to abort, and have a higher risk of being culled from the herd at an early age.

In addition to the occurrence of early abortion, the disease in beef herds is associated with the birth of live-born, premature, **low-birth-weight** calves. Depending upon the degree of prematurity, these calves can be kept alive with intensive care during the neonatal period.

Most congenitally infected calves are born alive without clinical signs. Congenital infection can occasionally be manifest with ataxia, loss of conscious proprioception, paralysis, and other **neurological deficits** in the new-born calf,[27] but the majority of congenitally infected calves are clinically normal and, surprisingly, epidemiological studies suggest that congenital infection does not necessarily have a detrimental effect on calf health and survival.[28]

1510
1511

N. caninum infection has been demonstrated in the nervous system of a **horse** with progressive debilitation, followed by sudden onset of neurological disease with paraplegia.[29] It appears a rare cause of neurological disease in horses but should be considered in the differential diagnosis of equine protozoal myeloencephalitis.

26.4.6

CLINICAL PATHOLOGY

Serological examination is with the indirect antibody fluorescent antibody test (IFAT), or by ELISA, and there is good agreement between the two tests. ELISA tests based on recombinant protein have higher sensitivities and specificities than that based on whole-tachyzooite lysates.[30] The IFAT is highly sensitive and specific for detection of maternal infection[31] and is commonly used. One study compared IFAT titers in maternal sera from 40 cows whose fetuses had been examined for neosporosis by immunohistochemistry. Of the 22 confirmed cases, 21 cows had titers of >1 in 640, whereas only one of the 18 negative cases had a titer of this magnitude.[32] The persistence of titers following infection is uncertain, and they may fluctuate during pregnancy. A positive titer in a cow that has aborted indicates exposure but not causality. Recently, IgG avidity patterns have been used to determine the duration of infection.[33,34]

Diagnosis is also made by the detection of antibody in **fetal pleural fluid or sera**,[31] and IFAT antibody has been found in the sera of from 50 to 65% of immunohistochemistry-confirmed cases of neospora infection, but not in fetuses under 4 months of gestational age.[35,36] Antigen can also be detected by PCR.[37]

26.4.7

NECROPSY FINDINGS

Gross findings are of autolysis. The brain may be autolysed, but should still be submitted for examination along with heart, liver, and placenta if available. Histological lesions are of multifocal encephalitis, myocarditis, and periportal hepatitis. Liver lesions may be more prominent in epizootic abortions. Immunohistochemistry using anti-*N. caninum* serum is used to identify tachyzooites in tissues, and the brain is the organ with the highest detection rate.[38] Immunohistochemistry is specific, but insensitive, in diagnosing fetal neosporosis, and maternal serology should be used in conjunction.

26.4.8

TREATMENT

There is no treatment that can be used to curtail an ongoing abortion epidemic and possible drug therapies are generally not considered an option because of likely unacceptable milk and meat residues and withdrawal problems.[9]

26.4.8.1

DIFFERENTIAL DIAGNOSIS

Serology using IFAT can confirm infection in individual cows.

Because of the high prevalence of infection, and the occurrence of congenital infection, care must be taken in extrapolating the results of a single positive diagnosis to problems of abortion.[3] The high rate of natural congenital infection means that evidence of infection in an aborted fetus is not proof of causation of abortion, and fetal examination should be coupled with serological examination of aborting and non-aborting animals in the herd for statistical differences.

- Other causes of abortion in cattle
- Weak calf syndrome.

26.4.9

CONTROL

All efforts should be made to exclude the possibility of dog **fecal contamination** of cattle feed and water and of the grazing environment.[39] **Placentas, aborted fetuses, and dead calves** should be removed and disposed of so that the definitive host and cattle cannot get access to them.

Congenitally infected cows are at high risk for abortion, and abortion rates in infected herds can be substantially reduced by **culling** these animals.[34,40,41] Congenitally infected calves can be identified by serology on precolostral blood samples and culled at a young age. If precolostral blood sampling is not feasible, examination of sera at 6 months of age will determine infected calves, positive titers indicating either congenital infection or postnatal infection.[42] Animals purchased into the herd should be seronegative.

It is possible that strategic therapy of pregnant cows with an appropriate antiprotozoal drug could abort the infection. This could be effective in beef cattle, but would probably not be legal, or appropriate, in lactating dairy cattle.

Whereas evidence for increased risk for neospora abortion due to immunosuppression resulting from concurrent infection with BVD virus is equivocal control of BVD infections should be a component of control programs for neosporosis.

A killed tachyzooite vaccine has been approved in the United States for use in pregnant cows and is available commercially. At present there are no controlled studies in the United States on its efficacy in mitigating the effects of bovine neosporosis in dairy cattle. A field trial in dairy herds in Costa Rica measuring abortion as the outcome showed a reduction in the incidence of abortion.[43] A study in growing beef cattle showed no significant effects between vaccinated and control animals in cumulative average daily gain or in food conversion efficiency.[44] Studies in sheep have shown that vaccination significantly reduces fetal loss in experimentally infected ewes. However, they showed that there was little protection against vertical transmission of *N. caninum* to the fetuses.[45,46]

Vaccination of dairy cattle may interfere with a herd test and cull policy.

26.5 CRYPTOSPORIDIOSIS

26.5.1 Synopsis

26.5.1.1 Etiology

Cryptosporidium parvum bovine genotype 2 and *C. andersoni*.

26.5.1.2 Epidemiology

Infection common in ruminant neonates. May cause diarrhea, especially if there is intercurrent infection with other enteropathogens, nutritional, or environmental stress.

26.5.1.3 Clinical findings

Malabsorption-type diarrhea.

26.5.1.4 Clinical pathology

Oocysts in feces demonstrated by immunofluorescent assay.

26.5.1.5 Lesions

Villous atrophy.

26.5.1.6 Diagnostic confirmation

Demonstration of lesions and organism.

26.5.1.7 Treatment

Supportive. Halofuginone or paromomycin if approved.

26.5.1.8 Control

Hygiene and management to ensure passive transfer of colostral antibodies and minimization of infection pressure.

26.5.2 ## ETIOLOGY

Cryptosporidium are protozoon parasites in the Phylum Apicomplexa. Currently, up to 14 species of *Cryptosporidium*, infecting mammals, fish, and birds, have been proposed but only two of these are of importance to agricultural animals. These include *C. parvum* which infects many different hosts including cattle, swine, horses, and small ruminants, and the calf genotype of *C. muris*, now called *C. andersoni*, which infects cattle.[1,2] *C. parvum* has two distinct genotypes known as human genotype 1 (also known as *C. hominis*) and bovine genotype 2. Both genotypes are capable of causing disease in humans. Livestock and horses are not commonly infected with genotype 1, although recently infections have been experimentally produced in lambs and piglets[3] and mixed infections with genotypes 1 and 2 have been observed in calves.[4]

Cryptosporidium parvum is a **common infection** in young ruminants and is found in many species of mammals including humans. There has been controversy about the role of *C. parvum* as a causative agent of diarrhea because infection can be found in normal healthy animals. However, it is considered a significant cause of varying degrees of naturally occurring diarrhea in neonatal farm animals. Most commonly, the agent acts in concert with other enteropathogens to produce intestinal damage and diarrhea.

26.5.3 ## EPIDEMIOLOGY

26.5.3.1 ### Occurrence and prevalence

Cryptosporidiosis has been recognized worldwide, primarily in neonatal calves, but also in lambs, goat kids, foals, and piglets.[5–9] Many studies report prevalence of infection but this does not imply clinical disease.

26.5.3.1.1 #### Calves

Infection is common in calves but reported prevalence rates of *Cryptosporidium* in feces vary widely. Prevalence ranging from 1.1% in a random sample of adult cattle feces in California[10] to 79% in symptomatic calves in Maryland, USA have been reported.[11] *Cryptosporidia* have been detected in 70% of 1 to 3-week-old dairy calves based on a single examination of feces.[12] A single sampling in a nationwide survey of 7369 calves on 1103 farms in the United States found infection on 59.1% of farms, and in 22.4% of

calves.[13] Daily sampling of calves in the first 4 weeks of life show higher rates of infection and a **period prevalence** of infection as high as 100%.[14–17] There is also **high site prevalence**.

A 6 year longitudinal study, on a lowland farm in the United Kingdom, of patterns of fecal excretion of *C. parvum* in beef cattle, dairy cows, home bred and purchased calves, lambs, rodents in the farm building environment and in the pastures, showed that the parasite was endemic and persistently present in all animal species tested. It found that patterns of infection were variable and that short-term or point prevalence sampling would be unlikely to provide a representative picture of infection rates. Prevalence rates and oocyst numbers in feces were highest in young animals.[17]

Infection can be detected as early as 5 days of age, with the greatest proportion of calves excreting organisms between days 9 and 14.[14–17] This is also the period of greatest **intensity** of excretion of the organism in the feces of individual calves.

Infection of the calf is followed by the development of resistance to reinfection, and oocyst excretion is less common and intermittent in older and adult cattle,[18,19] although high excretion rates are found in adult cattle in some herds.[20]

Most prevalence studies have found little association between infection and diarrhea, but there are many reports that associate infection in calves with diarrhea occurring between 5 and 15 days of age.

26.5.3.1.2

Sheep and goats

C. parvum is also a **common** enteric infection in **young lambs** and **goats**, and diarrhea can result from a monoinfection, but more commonly is associated with mixed infections. The age pattern of infection and excretion of the organism is similar to that in calves.[21] Infection can be associated with severe outbreaks of diarrhea, with high case fatality in lambs from 4 to 10 days of age[21–24] and goat kids from 5 to 21 days of age.[21]

26.5.3.1.3

Pigs

Cryptosporidial infection in pigs occurs over a **wider age range** than in ruminants and has been observed in pigs from 1 week of age through to market age. In a retrospective study of piglets submitted to a diagnostic laboratory over a 4-year period, cryptosporidia were detected histologically in 5.3% of about 3500 piglets.[25] Infection is most common

between 6 and 12 weeks of age.[26] The majority of infections are **asymptomatic**, and the organism does not appear to be an important enteric pathogen in this species,[26,27] although it may contribute to postweaning malabsorptive diarrhea.

26.5.3.1.4

Foals

Cryptosporidial infection in foals appears **less prevalent** and occurs at a later age than in ruminants, with excretion rates peaking at 5–8 weeks of age.[28] Infection is not commonly detected in yearlings or adults.[28,29] Most studies indicate that cryptosporidiosis is not a common disease in foals, and infections in immunocompetent foals are usually subclinical.[26,28] Diarrhea is recorded in foals from 5 days to 6 weeks of age including a report of an outbreak lasting one month where 9 of 30 foals aged between 4 days and 3 weeks of age were affected with a case fatality rate of 33%.[30] Persistent clinical infections occur in Arabian foals with inherited *combined immunodeficiency*.[31]

26.5.3.1.5

Farmed deer

Cryptosporidiosis is also recorded in young deer and can be a cause of diarrhea in artificially reared orphans. Infection has also been recorded in red deer calves dying at 24–72 hours of age following a syndrome of severe weakness and depression accompanied by a terminal uremia.[32]

26.5.3.2

Source of infection and transmission

Experimental infections have shown that a small number of oocysts are required for infection. The replicative cycle in the intestine amplifies a minor infective dose and studies in gnotobiotic lambs indicate a minimum **infectious dose** as low as one oocyst. The source of infection is **feces** which contain oocysts that are fully sporulated and infective when excreted. Large numbers are excreted during the patent period in calves resulting in heavy environmental contamination. Transmission may occur directly from calf to calf, indirectly via fomite or human transmission, from contamination in the environment or fecal contamination of the feed or water supply. Infection into the environment of newborn animals, and an increase in contamination of their immediate environment occurs as the result of a **periparturient rise** in the fecal excretion of oocysts by the dam. This has been recorded in ewes,[33] in a beef cattle herd where the rate of infection and the number of

1512
1513

oocysts in cattle feces increased significantly at one week post calving[34] and in some dairy herds.[35,36] Genotype 1 of *C. parvum* is not host-specific and infection from **other species**, such as rodents or farm cats, contaminating calf feeds, is also possible.

26.5.3.3

Risk factors

The factors that make animals susceptible to infection and that predispose infected animals to develop clinical disease are not well understood. Disease in agricultural animals associated with infection with *Cryptosporidium* is associated with infection with *C. parvum* and there is little evidence that infection with *C. andersoni* is associated with disease. Commonly, other enteric infections are present where there is disease attributed to *Cryptosporidium*. The site of infection with *C. parvum* is on the enterocyte where it results in cell damage, loss of brush border enzymes and a reduction of villous surface area.

26.5.3.3.1

Pathogen risk factors

Oocysts are resistant to most **disinfectants** and can reportedly remain viable for about 18 months in a cool, damp or wet environment, can survive for several months in soil and slurry[11,37] but are susceptible to desiccation and temperatures above 60°C.[38] The infectivity of the oocysts can be destroyed by ammonia, formalin, freeze-drying and exposure to temperatures below 0°C (32°F) and above 65°C (149°F). Ammonium hydroxide, hydrogen peroxide, chlorine dioxide, 10% formol saline and 5% ammonia are effective in destroying the infectivity of the oocysts. The infectivity of oocysts in calf feces is reduced after 1–4 days of drying.[39,40]

26.5.3.3.2

Concurrent infections

Concurrent infections with other enteropathogens, especially rotavirus and coronavirus, are common and epidemiological studies suggest that diarrhea is more severe with mixed infections. The rates of single and mixed infections vary with different studies. In general, mixed infections are most common, but cryptosporidial infection can be significant in its own right. For example, in two studies involving diarrheic calves submitted to diagnostic laboratories, cryptosporidia were the only pathogens isolated in 51% and 55% of the cases, while in 25% and 39% of cases the protozoan agent was found in combination with rotavirus and/or coronavirus.[41,42] **Immunologically compromised** animals are more susceptible to clinical disease than immunocompetent animals, but the relationship between disease and failure of passive transfer of colostral

immunoglobulins is not clear. The disease can be reproduced in both colostrum-deprived and colostrum-fed calves and, in the field, clinical disease can occur in calves and foals with adequate passive transfer of colostral immunoglobulins. However, the shedding of the organism has been observed to be higher in calves with low absorptive efficiency of IgG from colostrum and low serum IgG concentrations.[43]

26.5.3.3.3 Season

In one series of observations there was a tendency for the prevalence of infection to be higher during the winter months of the year when the calves were confined, which suggests a build-up of contamination,[44] but seasonal difference in prevalence is not marked and clinical disease can occur at all seasons.

26.5.3.3.4 Interactions

Case fatality rates in cryptosporidiosis are generally low unless there are other complicating factors. In addition to concurrent infections, these include energy deficits from inadequate intake of colostrum and milk, and chilling from adverse weather conditions.

26.5.3.3.5 Age

Age-related resistance, unrelated to prior exposure, has been observed in lambs[45] but not calves.[46] Infection results in the production of parasite-specific antibody, but both cell-mediated and humoral antibody are important in protection, as well as local antibody in the gut of the neonate.[47,48]

26.5.3.4 Experimental reproduction

The disease has been reproduced in colostrum-deprived calves, lambs and kids, in many studies.

26.5.3.5 Zoonotic implications

Infections in domestic animals and pets may be a reservoir for infection of susceptible humans. In humans, cryptosporidium is considered to be a relatively common non-viral cause of self-limiting diarrhea in immunocompetent persons, particularly in children. In symptomatic immunocompetent patients, cryptosporidiosis most commonly presents with

diarrhea that can lead to rapid weight loss and dehydration and require parenteral fluid therapy. The disease is usually self-limiting, symptoms normally lasting between 3 and 12 days. In **immunologically compromised** persons, clinical disease may be severe. This is particularly serious in human patients with acquired immune deficiency syndrome. The infection is transmitted predominantly from person to person, but direct infection from animals, and indirect water-borne infection from contamination of surface water and drinking water by domestic or wild animal feces can also be important. Animal manures and slurry may contain *C. parvum* and there is potential for contamination of the food chain as a result of run-off into adjacent surface waters or from direct application of the untreated wastes to crops. Recently, this risk for human infection has been a cause of public concern but this concern has been somewhat mitigated by the recognition that the cattle genotype does not infect humans.

Direct animal contact can result in human infection where there is hand to mouth transmission and infection and disease is recorded in veterinary students[49] and is a concern for children at fairs, petting zoos and in educational visits in farm settings.[50] Cryptosporidiosis is one of a number of zoonotic infections that have recently emerged in these settings. The apparent increase in prevalence of these infections could be due to the general movement of populations from rural to urban communities and the consequent removal from early exposure to farm animal-derived zoonotic agents. Equally, it could result from better detection and reporting by public health authorities. Regardless, the risk for transmission of zoonotic agents associated with petting zoos, farm animal exhibits, and fairs etc, is real and veterinarians are increasingly asked for advice on this issue. This can be in association with an official capacity as a fair veterinarian or in consultation with farm owners, who desire to bridge the increasing estrangement of urban populations to farm activities by allowing farm tours which frequently involve younger ages and more susceptible humans.

Animal handlers on a calf farm can be at high risk of diarrhea due to cryptosporidiosis transmitted from infected calves, and immunocompromised people should be restricted from access to young animals, and possibly from access to farms. 1513 1514

26.5.4 PATHOGENESIS

The life cycle of *Cryptosporidium* consists of six major developmental events. Following ingestion of the oocyst there is excystation (release of infective sporozoites), merogony (asexual multiplication), gametogony (gamete formation), fertilization, oocyst wall

formation, and sporogony (sporozoite formation).[1,2,38] Thus the oocysts of *Cryptosporidium* spp. can sporulate within the host cell, in contrast to the oocysts of *Eimeria* and *Isospora* spp., which do not sporulate until they are passed from the host, and they are infective when passed in the feces.[3] The infection persists until the immune response of the animal eliminates the parasite. In natural and experimentally produced cases in calves, the cryptosporidia are most numerous in the lower part of the small intestine and occasionally in the cecum and colon. The prepatent periods range from 2 to 7 days in calves, and from 2 to 5 days in lambs. Oocysts are usually passed in the feces of calves for 3–12 days.

The intracellular stages of the organism are within a parasitophorous vacuole, which is confined to the microvillous region of the host cell. The cryptosporidia appear free in the lumen of the intestine and attached to the microvilli of the villous epithelial cells. The parasitophorous envelope of the trophozoites and schizonts are derived from the microvilli, and the intracellular location of the organism is confined to fusion of the organism, with the apical cytoplasm of the epithelial cells and their enclosure by host membranes. Thus the organism is intracellular but extracytoplasmic.

The pathogenesis of the diarrhea is unknown, but the varying degrees of villous atrophy suggest that digestion and absorption may be impaired, resulting in diarrhea. The experimental inoculation of gnotobiotic calves with a monoinfection of *Cryptosporidium* species treated with peracetic acid to destroy other possible enteropathogens results in lesions of villous atrophy and diarrhea, which indicates that the organism can cause intestinal lesions[51] without concurrent infection with other enteropathogens. There is also evidence of hyperplastic crypt epithelium, which along with damaged villous epithelium and atrophic villi indicates that the lesions develop as a result of accelerated destruction or loss rather than decreased production of epithelial cells.[51]

26.5.5 CLINICAL FINDINGS

There are no clinical findings characteristic of diarrhea due to infection with *C. parvum* in calves. In general, calves are usually 5–15 days old and have a mild to moderate diarrhea which persists for several days regardless of treatment. The age at onset is later, and the duration of diarrhea tends to be a few days longer, than the diarrheas associated with rotavirus, coronavirus, or enterotoxigenic *Escherichia coli*. Feces are yellow or pale, watery, and contain mucus. The persistent diarrhea results in marked loss of body weight and emaciation in some cases. In most cases, the diarrhea is self-limiting after several days. Varying degrees of apathy, reduced feed intake and dehydration are present. Only rarely does

severe dehydration, weakness and collapse occur, in contrast to other causes of acute diarrhea in neonatal calves. Case fatality rates can be high in herds with cryptosporidiosis when the calf feeder withholds milk and feeds only electrolyte solutions during the episode of diarrhea. The persistent nature of the diarrhea leads to a marked energy deficit in these circumstances and the calves die of inanition at 3–4 weeks of life. This syndrome may be particularly common in the winter months where there is additional cold stress affecting energy requirements.

In the experimental disease in calves, depression and anorexia are the earliest and most consistent clinical findings. Feed intake is reduced and, combined with the persistent diarrhea over several days, may cause emaciation. Recovery occurs between 6 and 10 days after the onset of diarrhea.

In the experimental disease in lambs and kids, depression, diarrhea, and reduced feed intake are common and recovery occurs within a few days. More severe clinical manifestations have been observed in the field in lambs subject to environmental cold stress and those that are energy deficient due to an inadequate intake of colostrum.

26.5.6

CLINICAL PATHOLOGY

Diagnosis of cryptosporidiosis is traditionally based on the detection of fecal oocysts. The oocysts can be detected in the feces by examination of fecal smears with certain stains, by fecal flotation, or by immunologically assisted methods. Current diagnostic techniques used in most clinical laboratories include the immunofluorescent assay visualization of fecal oocysts. It has been suggested that, if the diarrhea is associated with cryptosporidia, the feces should contain 10^5–10^7 oocysts per mL of feces.[52] The oocysts are small (5–6 μm in diameter), relatively non-refractile, and difficult to detect by normal light microscopy. They are readily detected by phase-contrast microscopy. The demonstration of oocysts concentrated from fecal samples is by centrifugal flotation in high specific-gravity salt or sugar solutions.

The modified Ziehl–Neelsen is a simple and rapid procedure well suited for large-scale routine diagnosis of cryptosporidia.[14,15] An immunofluorescence technique on fecal smears is available, as are immunoassays.[14,15,53]

26.5.7 NECROPSY FINDINGS

Varying degrees of dehydration, emaciation, and serous atrophy are present in calves that have had persistent diarrhea for several days. There is atrophy of villi in the small intestine. Histologically, large numbers of the parasite are embedded in the microvilli of the absorptive enterocytes. In low-grade infections, only a few parasites are present, with no apparent histological changes in the intestine. The villi are shorter than normal, and there is crypt hyperplasia and infiltration with a mixture of inflammatory cells.[51]

26.5.7.1 Samples for confirmation of diagnosis

- **Parasitology** – feces (microscopic examination, ELISA, FAT)
- **Histology** – formalin-fixed jejunum, ileum (several sites), colon.

26.5.7.1.1 DIFFERENTIAL DIAGNOSIS

The disease must be differentiated from other common infectious diarrheas in calves, which are covered in the section on acute undifferentiated diarrhea.

26.5.8 TREATMENT

26.5.8.1 Specific therapy

Several different types of antiprotozoal drugs and antimicrobials have been evaluated with no therapeutic effect.[54–56] The exceptions are halofuginone and paromomycin.

Halofuginone is reported to markedly reduce oocyst output and the severity of diarrhea and/or mortality in infected lambs[24] and naturally and experimentally infected calves.[57–59] Therapy with this drug significantly reduced the severity of diarrhea and dehydration compared with sulfadimidine therapy in calves[60] and a randomized double blind trial in calves has shown a significant prophylactic effect when given for 7 days from 1 day of age.[61] Preliminary studies suggest that an oral dose of 60–125 μg/kg BW daily for 7 days will protect against clinical disease and will markedly reduce oocyte excretion, but will allow some intestinal infection and thus the development of immunity. The results of these studies suggest that the drug prevents reinfection of the gut by sporozoites and recycling merozoites.

1514
1515

Paromomycin sulfate given orally at a dose of 100 mg/kg BW daily for 11 consecutive days from the second day of age proved successful in preventing natural disease in a controlled clinical field trial in goat kids[21] and to reduce but not completely prevent diarrhea in infected lambs.[62]

26.5.8.2

Supportive therapy

Affected calves should be supported with **fluids and electrolytes**, both orally and parenterally as necessary until spontaneous recovery occurs. Cows' **whole milk** should be given in small quantities several times daily to optimize digestion and to minimize loss of body weight. It is important to **continue to feed** milk to the full level of requirement despite the presence of diarrhea, as a reduction in intake may lead to death from inanition. Several days of intensive care and feeding may be required before recovery is apparent. **Parenteral nutrition** could be considered for valuable calves.

26.5.9

CONTROL

The disease is difficult to control. The rational approach to prevention is to **minimize transmission** between the source of the organism and neonatal farm animals, and between the animals. Reducing the number of oocysts ingested may reduce the severity of infection and allow immunity to develop. Calves should be born in a clean environment and adequate amounts of colostrum should be fed at an early age. Calves should be kept separate without calf-to-calf contact for at least the first 2 weeks of life, with strict hygiene at feeding. Disinfectants detailed above should be employed in hygiene.

Diarrheic calves should always be **isolated** from healthy calves during the course of the diarrhea, and for several days after recovery. Sick calves are commonly treated by the same person who feeds the healthy calves and great care must be taken to avoid mechanical transmission of infection. Calf-rearing houses should be vacated and cleaned out on a regular basis; an all-in all-out management system, with thorough cleaning and several weeks of drying between batches of calves, should be used.

Rats and mice and flies should be controlled where possible and rodents and pets should not have access to calf grain and milk feed storage areas.

26.5.9.1

Immunoprophylaxis

Hyperimmune bovine colostrum can reduce the severity of diarrhea and the period of oocyst excretion in experimentally infected calves and lambs.[63–66] Protection is not related to circulating levels of specific antibody but requires a high titer of *C. parvum* antibody in the gut lumen for prolonged periods.

Vaccination with lyophylized *C. parvum* given orally shortly after birth has given partial protection to experimental calves challenged at 1 week of age.[66,67] It was not effective in protecting against natural challenge in a field trial, presumably because natural infection occurred too early to allow development of immunity.[68] In the same trial, lactic acid-producing probiotics had no protective effect.

26.6 ## GIARDIASIS (LAMBLIASIS)

26.6.1 ### Synopsis

26.6.1.1 #### Etiology

Giardia duodenalis. Zoonotic and livestock-specific assemblages.

26.6.1.2 #### Epidemiology

High prevalence of infection in young farm animals. Fecal–oral cycle of infection from excreting young animals, the dam and fomite contamination in environment. Cross species and water transmission possible.

26.6.1.3 #### Clinical findings

Most infections asymptomatic. May result in intermittent pasty feces and growth suppression.

26.6.1.4 #### Clinical pathology

Demonstration of organism in feces by phase microscopy or fluorescent antibody.

26.6.1.5 #### Necropsy findings

Villus atrophy.

26.6.1.6 #### Treatment and control

Benzimidazoles, hygiene.

26.6.2 ETIOLOGY

Giardia duodenalis (synonyms *intestinalis*, *lamblia*) is a flagellate binucleated protozoan that infects a variety of vertebrates including mammals, reptiles, and birds. It is a major cause of diarrhea in humans and has been suspected of causing diarrhea in agricultural animals. Human and animal isolates are similar on the basis of morphology, enzyme activities, and restriction enzyme analysis, although there are differences in DNA banding patterns. 1515 Currently the numerous genetic variants from mammals are all placed in the one species and 1516 the genotypic designation of *G. duodenalis* is evolving, with groups, assemblages and genotypes all used. Cattle are susceptible to infection with genotypes in the zoonotic genotype Assemblage A, which infect several different animal species, and the livestock genotype, Assemblage E, which appears restricted to hoofed animals.[1]

The organism develops in the small intestine where it multiplies by binary fission on the surface of the intestinal mucosa in the trophozooite stage and is excreted in feces as a cyst.

26.6.3 EPIDEMIOLOGY

26.6.3.1 Occurrence

Giardial infection, as opposed to disease, has been reported from most continents and has been identified in **all of the common agricultural animals**. There is a wide variation in reported prevalence between regions, which probably reflects sampling strategies and detection methodologies.[2] Excretion of giardial cysts may be continual or intermittent in young animals. Most prevalence studies have been in calves, and reported point prevalence infection rates in different countries range from 1 to 100%, with the majority of studies showing between 20% and 80% of calves infected and **high farm prevalence rates**.[3–5]

A similar large range is evident in more limited studies in lambs, kids, foals, and piglets.[5] Longitudinal studies of excretion patterns in grazing beef cattle, feedlot cattle, dairy cattle, calves, and foals show infection rates approaching 100%.[1,6–10]

26.6.3.2 Source of infection

Young animals are the primary source of infection, infection being transmitted through the oral–fecal route. High excretion rates and excretion intensities in young animals result in the contamination of the **environment** and infection via fomites.

The **dam** is also a source of infection for the young. Relaxation of immunity in terminal pregnancy and a **periparturient rise** in giardial cyst shedding has been shown in ewes where cyst excretion increased 2 weeks prepartum, peaked at 0–4 weeks postpartum and fell to low levels at 6–8 weeks postpartum.[11] A similar periparturient rise is suspected to occur in mares.[6] Cross-infection from other species and infection from contaminated water and feed are other sources of infection.

26.6.3.3

Pathogen risk factors

The infectious dose of giardia is thought to be very small.[2] Giardia are relatively resistant to environmental influences and at 4°C can survive for 11 weeks in water, 7 weeks in soil and 1 week in cattle feces.[12] They do not survive freezing. They are resistant to chlorination and extensive disinfection of the environment of calves does not prevent reinfection.[2]

26.6.3.4

Animal and management risk factors

Age is a major determinant of infection, and excretion rates are much higher in the young of all livestock species than in adults.[13,14] Excretion rates in groups of calves are highest between 3 and 10 weeks of age with the number of cysts in feces highest at 1–6 weeks of age.[5] Cyst excretion falls after weaning, but may persist intermittently into adulthood.[14] Similar patterns are seen in lambs.[11] Infection in foals may initiate later than in ruminants and new infections can occur as late as 22 weeks of age.[6] The influence of age on infection in pigs may be confounded by prophylactic medicants routinely used in pig operations.[15] No effect of housing, feeding water management or season has been observed in cattle[4,13] but hygiene in management practices can affect the age at exposure and the exposure intensity, and can influence infection dynamics. The high and early infection rates in calves and lambs compared with other livestock species are probably a reflection of this. Pigs reared on wire floors are infected later in life than pigs reared on porous concrete floors.[16] The prevalence of infection is higher in calves left with their dams to nurse colostrum for 3 days than in calves removed from the dam at birth to individual housing and fed colostrum by nipple bottle.[17]

26.6.3.5

Experimental reproduction

Following experimental challenge in calves, there is a prepatent period of 7–8 days and the calves subsequently excrete large number of cysts for periods varying from 60 to 112 days without evidence of clinical disease.[18] Infection of 6-week-old specific-pathogen-free (SPF) lambs with *Giardia* trophozoites has resulted in the occurrence of episodes of diarrhea and soft feces that are temporally associated with the detection of *Giardia* cysts in feces.[19] When compared with controls, infected lambs had reduced rate of gain without reduction in food intakes and took longer to reach market weight.

26.6.3.6

Economic importance

Evidence for a significant pathogenic and economic importance for the majority of giardial infections in agricultural animals is not convincing.

26.6.3.7

Zoonotic implications

The majority of giardial infections in cattle are with the livestock-associated assemblage with a small proportion of infections with the zoonotic Assemblage A.[3,4,10] Contact with farm livestock is one risk factor for disease in humans.[20] The is considerable concern in public health circles that infection of humans could also occur via water bodies receiving agricultural effluent and pasture run off leading to drinking water contamination. There is also concern for fecal dispersion of *Giardia* in back country watersheds from pack animals.[21]

26.6.4

PATHOGENESIS

Ingested cysts release trophozoites, which multiply and colonize the small intestine. These adhere to the villi of the small intestine by means of a suction disc on the trophozoite's ventral surface to result in inflammatory cell infiltration, villus atrophy, a reduced **villus to crypt ratio** and a reduction in brush border disaccharidase enzymes.[18,22] Disease, if it occurs in domestic animals, is believed to result from nutrient malabsorption and consequent diarrhea.

26.6.5 CLINICAL FINDINGS

There are several reports that detail the demonstration of giardial infection in individual animals with a chronic, malabsorbtive type of diarrhea, and most imply an association with diarrheal disease.[5,13] Most of these are in young animals at an age when both undifferentiated diarrhea and *Giardia* cyst excretion are common, but the evidence for a causal association is not convincing. There are also a number of studies on the incidence of infection in animals that comment that infection is not accompanied by evidence of clinical disease.[3–5]

A controlled study demonstrating loose feces and reduced rate of gain in experimentally infected lambs gives some credibility to a pathogenic role for this organism.[19]

In calves and lambs, giardial infection has been associated with a semi-fluid, pasty, intermittent diarrhea containing mucus, lasting 2–3 days but up to 6 weeks in some animals, and growth depression despite a normal appetite.

26.6.6 CLINICAL PATHOLOGY

Giardia cysts can be demonstrated in feces by phase contrast microscopy or immunofluorescent microscopy following flotation. Saturated salt or sugar solutions may disfigure the cyst, and the demonstration of infection is best conducted by sucrose gradient or zinc sulfate solution flotation. Cesium chloride density gradient centrifugation may be more sensitive.[2] Immunofluorescence is more sensitive than microscopy for the detection of cysts.[2]

26.6.7 NECROPSY FINDINGS

Findings are in the upper small intestine and are **non-specific**. Reported changes are an increase in intraepithelial lymphocytes in the jejunum, with moderate to severe diffuse inflammation, villus atrophy, crypt distortion and a reduction in the villus to crypt ratio.[18,22] Trophozoites are present in the mucosa and mucosal scrapings of the small intestine.

26.6.8

TREATMENT AND CONTROL

Giardial infections in agricultural animals have been successfully treated with dimetridazole at a dose of 50 mg/kg BW daily for 5 days[17] and is also susceptible to furazolidone, but both drugs are illegal for use in food animals in many countries.

The **benzimidazoles**, albendazole (20 mg/kg BW daily for 3 days) or fenbendazole (10 mg/kg BW daily for 3 days) are effective in eliminating infection in calves.[23,24] The 3-day course is required for effective elimination and some calves become reinfected following treatment.[25]

Continuous therapy by the incorporation of fenbendazole in a free choice mineral to a concentration of 0.55% was not effective in reducing giardial infection in grazing steers.[26]

In the absence of an association with significant disease, control procedures for giardiasis have not been developed for livestock. Those described for reduction of exposure in the section on undifferentiated diarrhea are appropriate.

26.7 BESNOITIOSIS (ELEPHANT SKIN DISEASE)

26.7.1 Synopsis

26.7.1.1 Etiology

Intermediate host-specific tissue cysts of *Besnoitia besnoiti, B. caprae*, and *B. bennetti*.

26.7.1.2 Epidemiology

Endemic disease in some tropical and subtropical areas with high morbidity and low mortality. Rare disease elsewhere. Definitive host not known. Possible insect transmission of disease in cattle and goats.

26.7.1.3

Clinical findings

Anasarca, alopecia, hyperpigmentation and scleroderma and infertility.

26.7.1.4

Inspiratory dyspnea and loss of condition

Pin-point nodules (cysts) on the sleral conjunctiva, nasal, pharyngeal, and laryngeal mucosa.

26.7.1.5

Lesions

Parasitic cysts in dermis, subcutaneous, and other fascia.

26.7.1.6

Diagnostic confirmation

Demonstration of bradyzoites in skin biopsy or scleral conjunctival scrapings.

26.7.1.7

Treatment and control

Little information available.

Besnoitiosis is a parasitic disease of cattle, goats, horses, and certain wild animals, and infections in the chronic cystic stage can result in severe production loss.

26.7.2

ETIOLOGY

Besnoitia are coccidian parasites in the family Sarcocystidae. The life cycle involves a definitive host and an intermediate host. There are seven classified species, of which three occur in domestic livestock. These are *B. besnoiti* in cattle, *B. caprae* in goats, and *B. bennetti* in horses, donkeys, and mules. The other four *Besnoitia* species infect wildlife species. Cats are the definitive host for some *Besnoitia* infecting wildlife, but the definitive host(s) for the three domestic livestock species are unknown.[1–3] Recent studies suggest that *B. besnoiti* and *B. capri* are genetically identical, that they also have identical bradyzoite ultrastructure and that they may not be separate species.[2,3]

26.7.3 EPIDEMIOLOGY

26.7.3.1 Occurrence

Besnoitiosis in livestock occurs as outbreaks in some tropical and subtropical regions and sporadically in other areas. In endemic areas, the disease can affect a large proportion of the herd and cause significant economic loss.[1,4–6] **Bovine** besnoitiosis is recorded in the African continent, southern Europe, South America, Israel, Asia, and the Soviet Union; **caprine** besnoitiosis in Kenya, Uganda, Iran, and Kazakhstan; **equine** besnoitiosis in north and east Africa.

26.7.3.2 Risk factors

Besnoitia are relatively host specific. *B. besnoiti* infects cattle and in Africa also infects goats and wild ruminants. The Kenyan species of *B. caprae* does not infect cattle or sheep.[6] The natural means of transmission is not known, but is presumed to be by ingestion of oocysts from the definitive host(s). Infection with *B. besnoiti* and *B. caprae* can be transmitted experimentally with endozoites and bradyzoites, and mechanically by infections or biting flies.[1,4,5] Outbreaks of clinical disease in cattle or goats occur in fly seasons and it is postulated that biting insects may be important vectors. Transmission via semen from infected males is also postulated.[6]

26.7.3.3 Economic importance

B. besnoitia is an economically important parasite of cattle in Africa and Israel. Attack rates can be high and although mortality is generally low it can approach 10% in the chronic stages. There is loss of condition and fertility of males in both cattle and goats can be significantly impaired from chronic scrotal skin lesions. Skins have no value for tanning. Equine besnoitiosis appears to have rare occurrence.

26.7.4 PATHOGENESIS

Following infection of the intermediate host, the endozoites (tachyzoites) proliferate in macrophages, fibroblasts, and endothelial cells, causing **vasculitis** and thrombosis, particularly in capil-laries and small veins of the dermis, subcutis, and testes. They then mature to form bradyzoite cysts (cystozoites) within fibroblasts. Replication is accompanied

by cellular destruction and the release of inflammatory mediators resulting in anorexia, lethargy, testicular degeneration, generalized edema of the skin, alopecia, and scleroderma.[7,8] *Besnoitia* cysts form in high numbers in the dermis and subcutaneous tissue. Inspiratory dyspnea is associated with infection in the upper respiratory tract.

26.7.5 CLINICAL FINDINGS

26.7.5.1 Bovine besnoitiosis

Typical signs occur in two stages: the acute anasarca stage associated with the proliferation of endozoites and the chronic scleroderma stage associated with cyst formation.

26.7.5.1.1 Acute stage

There is fever, an increase in pulse and respiratory rates, and warm, painful swellings appear on the ventral aspects of the body, interfering with movement. There is also generalized edema of the skin. The superficial lymph nodes are swollen, diarrhea may occur, and pregnant cows may abort. Lacrimation and an increased nasal discharge are evident and small, whitish, elevated macules may be observed on the conjunctiva and nasal mucosa. The nasal discharge is serous initially, but becomes mucopurulent later and may contain blood. 1517 1518

26.7.5.1.2 Chronic stage

As the disease becomes more chronic, the skin becomes grossly thickened, corrugated, and there is alopecia. A **severe dermatitis** is present over most of the body surface. Affected bulls often become sterile for long periods, especially if the scrotal skin is affected. Cystic stages of the *Besnoitia* have been found in vascular lesions in the testes of affected animals and may be a major contributor to the sterility. **Cysts on the scleral conjunctiva** are considered to be of particular diagnostic significance.[4]

The case fatality rate is about 10% and the convalescence in survivors is protracted over a period of months. In endemic areas, the signs that attract clinical attention are alopecia, and severely thickened and wrinkled skin which is often thrown into folds around the neck, shoulder, and rump region and the carpal and tarsal areas. Small, subcutaneous, seed-like lumps can be palpated.[4] In cattle, infections of the teat skin may result in lesions around the mouth in suckled calves.

26.7.5.2

Caprine besnoitiosis

The acute stage is not commonly seen in goats, and the disease presents like the chronic stage in cattle,[5,9] with dyspnea and cutaneous lesions. The cutaneous lesion is a chronic dermatitis of the legs, particularly the carpal and tarsal areas, and the ventral surface of the abdomen. It varies from mild thickening with superficial scaling to marked thickening with hyperpigmentation and a serous discharge. The hair is sparse.

26.7.5.3

Equine besnoitiosis

Horses may show exercise intolerance, nasal discharge, and inspiratory dyspnea. Skin lesions, like those in cattle and goats, are present on the ventral abdomen and legs or the whole body surface.[8,10] Pin-point white nodules can be seen by endoscopy on the soft palate, pharynx, and larynx.[10]

26.7.6

CLINICAL PATHOLOGY

There is little information on hematology and blood chemistry. Hypergammaglobulinemia has been reported in one horse.[10]

Bradyzooite cysts containing a number of banana or spindle-shaped spores can be detected in scrapings or sections of skin, or scleral conjunctival scraping.[4] Ear-tip biopsies are commonly used in surveys of goats, and many infected animals show no clinical signs of infection. Serum antibodies to *Besnoitia* spp. are identifiable by an indirect immunofluorescence technique and by an ELISA, but the tests have only moderate sensitivity.[11,12]

26.7.7

NECROPSY FINDINGS

Necropsy lesions in cattle with the severe form of the disease are characterized by widespread vascular lesions and secondary lesions in skeletal and heart muscle, and lungs.

The parasite is evident in lesions on histological examination. In the chronic form in goats, multiple grayish-white cysts are found in the subcutis of the neck, limbs, thoracic region, and the intermuscular fascia. Cysts are also present in the nasal mucosa, larynx, soft palate, and trachea, and the scrotum and testes of males.[1,5]

26.7.8

DIAGNOSTIC CONFIRMATION

The most efficient and cost-effective method of diagnosis of clinical disease is the demonstration of *Besnoitia* bradyzoites in skin biopsy smears or scleral conjunctival scrapings.[4]

26.7.9

TREATMENT AND CONTROL

There is little information on treatment. Clinical cure of a donkey with a 9-month history of chronic skin disease is reported following prolonged oral administration of trimethoprim–sulfamethoxazole.[8] Animals should receive supportive therapy and be treated symptomatically for enteritis or dermatitis.

A vaccine containing *Besnoitia besnoiti*, grown on tissue culture, and originally isolated from blue wildebeest, has been used to vaccinate cattle. A durable immunity to the clinical form of the disease was produced in 100% of vaccinates, but subclinical infection at a low level did occur.[13]

26.8 # TOXOPLASMOSIS

26.8.1 ## Synopsis

26.8.1.1 ### Etiology

Toxoplasma gondii.

26.8.1.2 ### Epidemiology

Infection from the ingestion of oocytes excreted by cats. Swine can also acquire infection from ingestion of tissue stages of parasites in carrion.

26.8.1.3 ### Clinical findings

Abortion and stillbirths in ewes is the major veterinary manifestation, minor manifestations in all species are encephalitis, pneumonia, and neonatal mortality. Major importance as a zoonosis from organisms in meat.

26.8.1.4 ### Clinical pathology

Serological tests, which vary in sensitivity and specificity.

26.8.1.5 ### Lesions

Granulomatous lesions in organs of all species, with abortions, placentitis, and focal necrotic lesions in brain, liver, and kidney of aborted fetus.

26.8.1.6 ### Diagnostic confirmation

Demonstration of organism. PCR.

26.8.1.7 ### Treatment

Not usually indicated. Sulfamethazine and pyrimethamine in abortion outbreak.

26.8.1.8 ### Control

Reduce exposure to oocysts. In pregnant sheep, prophylactic feeding of monensin or decoquinate, vaccination.

26.8.2

ETIOLOGY

The causative agent *Toxoplasma gondii* is a systemic coccidian, a universal parasite, a sporozoan, and a member of the suborder *Eimeriina*. It is a specific parasite of the *definitive host* (**members of the Felidae family**), but has a wide range of intermediate hosts. There are three clonal lineages designated type I, II, and III which differ in virulence and epidemiological pattern. Strains isolated from animals are mostly genotype III.[1]

T. gondii has three infective stages:

1. Tachyzoites – the rapidly multiplying form of the parasite present during the acute stage of infection in the intermediate host
2. Bradyzoites – present in the tissue cysts
3. Oocysts (containing sporozoites) – present only in cat feces.

Oocysts are the **infective stage** of importance in farm animals, and the only environmental infective stage for herbivores. Oocysts excreted in the feces of cats can survive in soil for many months and are ingested by the intermediate (livestock) host, and the parasite invades tissues to produce tissue cysts. The invasion can include the fetus. An inoculum containing as few as ten oocysts can be infective for goats Tissue cysts in the intermediate host cause damage to the nervous system, myocardium, lung tissue, and placenta. Bradyzoites in animal tissues are a source for toxoplasmosis in humans and pigs.

26.8.3

EPIDEMIOLOGY

26.8.3.1

Occurrence

Toxoplasmosis occurs in domesticated and wild animals and birds in most parts of the world, although surveys indicate differences in area prevalence. The studies in farm animals have been summarized in the literature.[2–4]

A national survey in **swine** in the United States found a seroprevalence of 20%.[5] The rate of seropositivity was higher in breeding swine than in feeders, and there were geographical differences with the percentage of positive farms varying from 22% to 89% in different States. On a worldwide basis, the seropositive prevalence in swine is 22% with a range of 0–97%.[6] Equivalent figures for other species are: **sheep**, 21%; **goats**, 25%; **horses**, 15%.[3]

The true seroprevalence of toxoplasmosis in **cattle** is not known due to the inaccuracy of the standard serological tests for cattle.[2] The true seroprevalence in cattle is believed to be low, reflective of the relative unimportance of toxoplasmosis in cattle.[3]

While seroprevalence studies indicate relatively high rates of infection in farm animals, the infection is subclinical and *T. gondii* has virtually no importance as a cause of clinical disease in farm animals with the exception of that associated with abortion and neonatal disease in sheep. A major importance of toxoplasmosis in farm animals is its **zoonotic potential**.

26.8.3.2 ## Source of infection

26.8.3.2.1 ### Cat feces

The source of infection for sheep, cattle and horses is the **oocyst** passed in the feces of the cat family. In almost all agricultural areas the feces originate from the domestic cat or feral cats.

Cats become infected, and shed oocysts in their feces, as a result of ingesting tissues of intermediate hosts infected with the parasite. Commonly, these are rodents and small birds, but **all animals can be intermediate hosts** for *T. gondii*. Rodents pass the organism from generation to generation through congenital infection and thus can provide a reservoir of infection in an area for a long time with the potential for infection of cats and the triggering of massive oocyst contamination of the environment.[7]

The prevalence of infection is highest in young cats hunting for the first time. Following infection of the cat, the period of excretion of oocysts is short, approximately 2 weeks, but it is intense and several million oocysts are excreted in the feces. In a given environment the number of cats excreting oocysts in their feces at any point in time is likely to be quite small, but the contamination of the environment over time is significant.

Domestic and barn cats in farm environments tend to nest and to defecate in hay and straw mows, grain stores, or other loose piles of commodity feeds, thus providing the potential for direct infection of livestock feeds with *T. gondii*. Fields fertilized with manure and bedding from buildings that contain cats can also be a source of infection.[8] **Feral cats** bury feces superficially in the soil, but the action of earthworms and other soil inhabitants can bring infection to the surface to contaminate pastures. Feral cat families

can have territories of up to 250 acres and are capable of widely distributing the infective stage of the parasite.[7,9] Oocysts can be found in feed, water, and soil in the vicinity of livestock units.[10]

26.8.3.2.2 Other sources

Oocysts are also the major source of infection for swine, although it is possible for swine to be infected by the ingestion of tachyzoites or bradyzoites present in meat (**dead rodents**, cannibalized piglets, etc.) or through the ingestion of blood while **tail- or ear-biting**.[11] Toxoplasma infection has been shown in all wildlife mammalian species tested in the environment of swine units.[10] Direct sheep-to-sheep transmission by close contact with grossly infected placenta and transmission via the semen of infected rams could occur but are not believed to be of significance. However, a recent study in sheep has shown *T. gondii* to be present in the placental tissue of a high percentage of successful pregnancies and congenital infection may be an important method of maintenance of infection in sheep flocks in the absence of cats.[12]

26.8.3.3 Risk factors

26.8.3.3.1 Pathogen risk factors

Oocysts are extremely resistant to external influences and can survive in the environment for at least 1 year. They can **overwinter** in cold climates, but are less viable in arid environments. Fifty grams of infected cat feces can contain as many as 10 million oocysts and infection in farm animals can be established by the ingestion of fewer than 40 oocysts.[3,13] Oocysts are destroyed by exposure to temperatures between 90°C (194°F) for 30 seconds and 50°C (122°F) for 2.5 minutes.

26.8.3.3.2 Environmental and management risk factors

In sheep, a high rate of infection has been shown to be related to a **high rainfall**, which allows longer survival of oocysts on pasture. The prevalence of infection in small ruminants is much lower in hot, dry arid countries than in those with wet climates.[14]

Sheep raised in **cat-free areas** have almost no toxoplasmosis, whereas sheep raised in similar environments with cats can have an infection rate as high as 32%.[15] In many recorded outbreaks with high prevalence rates in sheep and goats there has been serious

exposure to stored feed containing cat feces. Cat access to sows is also a risk factor for disease in swine.[16]

Other management risk factors include **housing**. Swine housed outdoors are at significantly greater risk for infection in some areas,[17] and prevalence is lower in sows that are kept totally confined.[18] Pig meat is a significant source of infection in humans and the trend to 'animal friendly' outdoor rearing may increase the risk to humans.

Seroconversion may occur more frequently in sheep during the summer pasturing period than during winter housing.[19]

26.8.3.4 Experimental reproduction

26.8.3.4.1 Sheep

Experimental disease can be achieved by challenge with oocysts, tissue cysts and tachyzoites.[13] The ewe may show a febrile response during the parasitemic phase 5–12 days following infection. Abortion and fetal mortality occur in sheep that suffer a primary infection during pregnancy. The organism invades the placenta and can be detected in the fetus between 5 and 10 days after the onset of the parasitemia.[7] Infection may result in resorption, abortion or the birth of stillborn or congenitally infected live lambs. Infection in early pregnancy (less than 60 days) before the fetus acquires immunological competence usually results in embryonic death and resorption and a barren ewe. Infection in mid-pregnancy generally results in abortions and the birth of stillborn lambs whereas ewes infected in late pregnancy (greater that 110 days) may give birth to live but congenitally infected lambs.

26.8.3.4.2 Cattle

Cattle are **relatively resistant** to infection. Diarrhea, anorexia, poor weight gain, depression, weakness, fever, and dyspnea follow challenge of calves with pathogenic strains. With strains of low virulence there is a mild fever and lymphadenopathy, and the organisms are detectable only in the lymph nodes and for only a few weeks. Adult cows are also relatively insusceptible and it is apparent that cattle do not readily acquire persistent *T. gondii* infections, probably because of **rapid elimination** of parasites from the tissues.[2,9,20] Many historical reports of outbreaks of toxoplasmosis in cattle were probably sarcocystosis, as serological tests employed in most studies lacked sufficient

specificity for diagnosis of toxoplasmosis.[1,2] *T. gondii* is not important in causing abortion or clinical disease in cattle, but is recorded.[21]

26.8.3.4.3

Other ruminants

Large doses of oocysts fed to goats cause a febrile, anorectic, fatal illness, and pregnant does abort.[9] The pathogenesis of the abortion is as for sheep. The reaction in buffalo calves is described as peracute, with pulmonary consolidation, necrotic foci in all organs, and fluid accumulations in body cavities.

1519
1520

26.8.3.4.4

Pigs

Infection is relatively easily established in pigs, but is generally not associated with clinical disease or only with a short period of fever and growth suppression. There is a greater susceptibility to infection in young pigs, with piglets below the age of 12 weeks much more susceptible than older animals. With a mild strain and pigs of 8–10 days of age, the reaction is minor, but day-old pigs may have a high mortality rate.[22] Infections induced by tissue cysts are generally less severe than those induced by the ingestion of oocysts and consist of inflammatory and degenerative changes in numerous organs as with other animal species. Congenital toxoplasmosis is not easily reproduced experimentally despite its association with syndromes of neonatal mortality in the field.[23]

26.8.3.4.5

Horses

These appear to be **relatively non-susceptible** to the development of the disease or the persistence of infection, and attempts at experimental transmission are rarely successful.

26.8.3.5

Economic importance

Abortion and neonatal mortality in sheep and goats are the major clinical manifestations of infection with *T. gondii* and result when primary infection occurs during pregnancy. Ovine abortion and neonatal mortality due to *T. gondii* are important problems in New Zealand, Australia, Canada, United States, and the United Kingdom; in most countries they are second in importance only to chlamydial abortion. Perinatal mortality rates (including abortions and neonatal deaths) in affected flocks may be as high as 50%, and in non-clinical flocks may still result in low rates of loss. In the United Kingdom, toxoplasmosis is

the primary cause of loss in 10–20% of flocks with an abortion problem, and has an annual incidence of 2% in the breeding ewe population.[7] Abortion, with associated mummification of fetuses and perinatal deaths, due to toxoplasmosis also occurs in goats.[2,21]

26.8.3.6

Zoonotic implications

Humans are intermediate hosts for *T. gondii*, and approximately one-half the population of the United States is infected.[3] Infection can result from the ingestion of oocysts from cat feces that contaminate waterways and food, that contaminate the hair of domestic dogs and cats, or that are inadvertently ingested because of poor hygienic practices. However, the major risk for human infection rests with ingestion of bradyzoites and tachyzoites in **meat** or tissues that are eaten or handled. The risk is with raw or undercooked meats. Beef is a minor source of infection, with pig and to a lesser degree sheep meat having greater risk.[3]

Tachyzoites are secreted in the milk of goats challenged with oocysts and **raw goats' milk** has a public health risk for toxoplasmosis, although the risk is minimal.[3,24]

There is usually no clinical disease in humans infected with *T. gondii*, or the disease is mild and self-limiting.[3] Significant disease can occur in humans suffering from acquired **immune deficiency** (**AIDS**) or malignancy, in those treated with cytotoxic or immunosuppressive drugs, and in the very young and the very old. There is also the risk in **pregnant women** for abortion or congenital infection of the fetus with resultant hydrocephalus, intracranial calcification, and retinochoroiditis. Maternal infection in the first and second trimester may result in severe congenital toxoplasmosis and death of the fetus in-utero and abortion. Later infection may result in the birth of apparently normal children that have a risk for developing chorioretinitis later in life.

Toxoplasmosis poses an **occupational risk** for veterinarians, farmers, and slaughterhouse workers who handle infected material. The risk is particularly high with contact with lambing ewes in infected flocks; veterinarians and farm workers, especially if pregnant or immunocompromised, should take precautions to avoid infection when handling infected material.

26.8.4

PATHOGENESIS

T. gondii is an **intracellular parasite** that attacks most organs, with predilection for the **reticuloendothelial and central nervous systems**. Sporozoites from oocysts, or bradyzoites

from tissue cysts, invade and penetrate cells by an active process[25] and multiply in the intestinal epithelium. After invasion of a cell, the parasite multiplies and eventually fills and destroys the cells. Liberated toxoplasma reach other organs via the bloodstream after release from their development site. The stage of **parasitemia** commences approximately 5 days after initial infection and declines with the development of immunity 2–3 weeks after infection, at which stage the organism localizes in tissue cysts.

The clinical character of the disease varies with the organs attacked, which itself varies depending on whether the disease is congenital or acquired. The principal manifestations are encephalitis when infection is **congenital**, and febrile exanthema with pneumonitis and enterocolitis when very heavy infections occur **postnatally**. However, the vast majority of infections occur without any clinical signs, and tissue cysts can be found in many animals and appear to cause no harm. When the immunity of the animal falls because of stress, disease or immunosuppressive therapy, tissue cysts rupture and large numbers of inflammatory cells invade surrounding tissue. The characteristic granulomatous lesions are thought to be the result of a hypersensitivity reaction.

26.8.4.1

Pregnant sheep and goats

Abortion and fetal mortality occur in sheep that suffer a primary infection during pregnancy. In the ewe, the infection is limited by the developing immune response; however, this does not limit the infection in the placenta. The fetus and the ability of the fetus and its associated placenta to respond with a protective response depends upon the age of the fetus at the time of infection.

Immunocompetence to *T. gondii* is not present before 60 days of gestation[7] and infection in early or mid-pregnancy results in fetal death, with resorption or mummification. Some lambs infected in mid-pregnancy may survive to near term and be stillborn, or may survive to parturition but are weak and die shortly following birth. Parasite multiplication in the placenta results in multiple foci of necrosis, and placental abnormality may contribute to abortions and to the birth of weak lambs. Also, congenital brain infection may result in locomotory and sucking dysfunction. Only those sheep that become infected during pregnancy abort. With infection in late pregnancy, the fetus can mount an immune response and is usually born live, infected, and immune. Infection of pregnant and non-pregnant sheep provokes sufficient immunity to prevent abortion in future pregnancies.

26.8.5 CLINICAL FINDINGS

The clinical syndrome and the course of toxoplasmosis vary a great deal between species and between age groups. The only clinical syndrome recognized with any regularity in the field is abortion and neonatal mortality in sheep. The other, less common, syndromes are as follows.

26.8.5.1 Cattle

In cattle, the disease usually runs an acute course – fever, dyspnea, and nervous signs, including ataxia and hyperexcitability, in the early stages, followed by extreme lethargy. Stillborn or weak calves that die soon after birth may also be observed. Toxoplasmosis plays no significant role in bovine abortion. Congenitally affected calves show fever, dyspnea, coughing, sneezing, nasal discharge, clonic convulsions, grinding of the teeth, and tremor of the head and neck. Death occurs after a course of 2–6 days.

1520 1521

26.8.5.2 Pigs

Pigs are **highly susceptible**, and in outbreaks pigs of all ages can be affected. In adult pigs there is debility, weakness, incoordination, cough, tremor, and diarrhea, but no fever. Young pigs are often acutely ill with a high fever of 40–42°C (104–107°F), they develop diarrhea, and die after a course of several weeks. Pigs of 2–4 weeks of age have additional signs, including wasting, dyspnea, coughing, nervous signs, especially ataxia. Pregnant sows commonly **abort**, piglets are premature or **stillborn**, or survive and develop the above syndrome at 1–3 weeks of age. Toxoplasmosis may be the cause of a resident problem of abortions and stillbirths in a pig herd.

26.8.5.3 Sheep

In sheep, although a syndrome of fever, dyspnea, generalized tremor, abortions, and stillbirths can occur, the clinical manifestation of the systemic disease in the ewe is rare. The principal manifestations of toxoplasmosis in sheep are fetal resorption, abortion, the birth of mummified or stillborn lambs, neonatal death, and the birth of full-term lambs that show locomotor and sucking disorders.

Abortion commonly occurs during the last 4 weeks of pregnancy and the rate may be as high as 50%. Full-term lambs from infected ewes may be born dead, or alive but weak, with death occurring within 3–4 days of birth. Lambs affected after birth show fever and

dyspnea, but a fatal outcome is uncommon. Fetal resorption can occur in ewes infected in early pregnancy.

26.8.5.4 Goats

In goats, caprine toxoplasmosis is manifested by perinatal deaths, including abortions and stillbirths. Systemic disease, with a high case fatality rate, can occur, especially in young goats.

26.8.5.5 Horses

Clinical disease is **rare** in horses.

26.8.6 CLINICAL PATHOLOGY

Serological tests available for the detection of humoral antibodies to *T. gondii* include the Sabin–Feldman dye test, the indirect hemagglutination assay, the indirect fluorescent antibody test (IFAT), the modified agglutination test (MAT), the latex agglutination test (LAT), the enzyme-linked immunosorbent assay (ELISA), and the immunosorbent agglutination assay test (IAAT). Serological tests are commonly used to determine the presence of toxoplasmosis, but the **sensitivity and specificity vary** with the test and with the same test between species. Tests in cattle pose a particular problem.[1,2,26–28] In cattle and swine, agglutination tests that use whole *T. gondii* tachyzooites are suitable, but the latex agglutination tests that use soluble antigens, and the Sabin–Feldman dye test lack sensitivity and specificity.[26,27]

26.8.6.1 Sheep abortion

Serological testing to establish toxoplasmosis as the cause of abortion is of limited value. A negative titer will rule out toxoplasmosis but, since antibody persists for years, a positive titer will only indicate that the animal has been exposed to infection at some stage of her life. Seroprevalence rates are normally high in sheep and swine. **Rising titers** in paired samples are more informative, but may be of limited value in the diagnosis of abortion in sheep where infection and antibody response may precede the abortion storm. In sheep, it is more informative to test **pleural or peritoneal fluid** of aborted fetuses for the presence of antibody. An IgG avidity ELISA using a dominant membrane protein (P30) of *T. gondii* is claimed to be able to differentiate between acute and chronic infections in sheep.[29]

Polymerase chain reaction assay (PCR) can be used to detect *T. gondii* in infected fetal tissues.[30]

26.8.6.2 Infection in pigs

MAT, IFAT and a commercially available ELISA test have been shown to have equivalent sensitivity and specificity in swine and can be used for serological and epidemiological studies in this species.[31,32] Meat juice taken from heart or tongue from pig carcasses after slaughter can be tested for antibody and a PCR for detection of the infection in meat is described.[33]

26.8.7 NECROPSY FINDINGS

Multiple, proliferative, and **necrotic granulomata** are characteristic of toxoplasmosis, and in cattle the lesions may undergo calcification. The lesions occur most commonly in the nervous system, myocardium, and lungs. When there is visceral involvement, pneumonitis, hydrothorax, ascites, lymphadenitis, intestinal ulceration, and necrotic foci in the liver, spleen, and kidneys may be observed.

26.8.7.1 Abortion

In **sheep**, there may be involvement of the uterine wall, the **placenta**, and the fetus. The lesions in the fetal lambs are usually limited to focal necrotic lesions in brain, liver, kidney, and lungs; pathological lesions are much more common and severe in the **placenta**.[12,34] The characteristic lesions are confined to the cotyledons and consist of foci of inflammation and necrosis, which may produce macroscopically visible **white foci**. On histological examination, granulomatous, necrotic lesions can be found in the viscera and in the brain. Toxoplasma can be found in the cells of most organs, particularly the lungs and brain. The organism is not easily demonstrated in aborted sheep fetuses or in their placentas.

In **swine**, the prominent lesions are necrotic placentitis, non-suppurative encephalomyelitis, and myocardial degeneration. In contrast to sheep, grossly visible areas of necrosis are not present in the placenta, but numerous organisms may be visible on microscopic examination of the placenta.[23] Experimentally, there is also myocardial degeneration, necrosis, and mineralization. It is probable that many cases previously diagnosed as **bovine** toxoplasmosis were actually cases of neosporosis or sarcosporidiosis.

Immunohistochemical staining can be used to identify the parasite in formalin-fixed material. Serological testing of fetal thoracic fluid can be useful in those fetuses that are immunocompetent at the time of abortion. A PCR can be used for the detection of antigen in ovine tissue and can be used on autolysed tissue.[24]

On rare occasions, bioassay must be performed to confirm the identity of the parasite and is the most sensitive method of detecting infection. Aseptically collected brain, lung, and diaphragm is administered orally, or by intracerebral or intraperitoneal injection, to mice, or orally to cats. A positive diagnosis depends upon the presence of toxoplasma cysts in the brains of the mice 8 weeks after the injection or the secretion of oocysts by the cat. Cats are a more sensitive assay because of the volume of tissue that can be tested.

26.8.7.2 Samples for confirmation of diagnosis

- **Parasitology** – fresh or chilled brain, lung, placenta (BIOASSAY) (rarely required)
- **Serology** – fetal thoracic fluid (IHA)
- **Histology** – placental cotyledons, lung, liver, brain, spinal cord, kidney, heart (LM, IHC).

26.8.7.2.1 DIFFERENTIAL DIAGNOSIS

Toxoplasmosis is rarely considered in a primary diagnostic list other than with problems of abortion and associated neonatal mortality. The differential diagnosis of abortion in cattle is dealt with under brucellosis, in sheep under brucellosis, and in pigs under leptospirosis. The causes of encephalitis in animals are listed under that heading, and of pneumonitis under pneumonia.

1521

1522

26.8.8 TREATMENT

Treatment with a combination of sulfamethazine and pyrimethamine has proved effective in mitigating the effects of experimentally induced toxoplasmosis in pregnant ewes; it should be considered for therapy in the face of an outbreak of toxoplasma abortion. Treatment was administered over 3 days for three periods with an interval of 5 days between the start of each treatment period.[35] These drugs are effective against the proliferating parasites in the acute stage of the disease, but will usually not eradicate infection and have limited activity on the organisms in tissue cysts.

26.8.9 CONTROL

There are two concerns in the control of toxoplasmosis in agricultural animals. The first is the concern to reduce the economic effects of infection in agricultural animals, and the second is to reduce the risk for human disease associated with consumption of infected meat.

26.8.9.1 Farms

26.8.9.1.1 Cat control

The elimination of cats in the farm environment will preclude feed contamination and contamination of pasture areas. While it is possible to **ban domestic cats** from the farm, this will not, in general, totally eliminate the risk for toxoplasmosis due to the range of activities of cats from adjacent areas, the presence of feral cats and the occurrence of wind-borne spread of oocysts.[9] Nevertheless, risk for infection will be reduced by eliminating cats from the farm environment or restricting them to **neutered** animals. Where **possible, feeds should be stored in cat-proof areas**. In swine units, control of rodents and of access of pigs to any **carrion** is an important control measure. On all farms, the carcasses of infected or suspect animals should be totally destroyed, or at least be made inaccessible to carnivores.

26.8.9.2 Serological testing

With sows housed both indoors and outside, serological testing to determine seroprevalence and seroconversion associated with the two housing areas may determine if housing management needs change. Serological testing can also be used to determine housing/pasture areas of risk for sheep, risk for abortion in sheep, and whether anti-toxoplasmal drugs or vaccination should be used for protection.

There is an effective and long-lasting immunity following primary toxoplasma infection and ewes that have aborted should be kept in the flock. Exposure of ewes to natural infection in a contaminated environment prior to breeding would be an effective method of preventing reproductive disease, but is difficult to achieve with certainty.

26.8.9.3

Prophylaxis

Feeding **monensin** at a dose of 15 mg/head per day during the first 100 days of pregnancy has been shown to reduce lamb loss following experimental infection, as has decoquinate fed at 2 mg/kg daily.[12,28] **Decoquinate** is more palatable and has less risk of toxicity,[28] and medication offers an option for control in ewes that are seronegative for *T. gondii* antibodies and likely to be exposed in pregnancy to feed, water or an environment contaminated with toxoplasma oocysts. Both drugs are best fed to ewes before they encounter infection and are not effective as therapeutic agents.

26.8.9.4

Vaccination

Tachyzoites from an incomplete strain, S48, of *T. gondii* are used in a vaccine for sheep which is available commercially in some countries. S48 tachyzoites readily infect seronegative sheep, but do not initiate chronic infection or tissue cysts and the parasite cannot be demonstrated in muscle or brain 6 weeks after vaccination.[36,37] Ewes should be vaccinated at least 3 weeks before mating, and a single injection will protect the life of the sheep. In flocks where toxoplasmosis is a cause of lamb loss, initial vaccination of the whole flock followed by vaccination of replacement ewes is a better economic option than that of just vaccinating replacement ewes.[38] Vaccination does not entirely protect the pregnant ewe against parasitemia or the infection of the fetus following challenge with virulent *T. gondii* oocysts, but there is a significant reduction in the birth rates of non-viable lambs. It has been postulated that vaccination results in reduced numbers of tachyzoites invading the gravid uterus or fetus, with a consequent reduced potential for inducing significant pathology in the placenta and the fetus.[36] The immunity appears to be cell-mediated.[37] Experiments with an adjuvenated vaccine in pigs show protection from clinical challenge and a reduction in recoverable toxoplasma from tissues of vaccinated challenged pigs.[39]

26.8.9.5

Reduction of zoonotic risk from meat

Oocysts from cat feces are a major cause of infection in man, but the ingestion of cysts in meat from sheep, swine and, to a lesser extent, cattle is also a major cause of human infection. The implementation of control procedures on the farm will reduce that risk and the major influence will be by the reduction or elimination of cats on the farm.[37] The

infectivity of meat can be destroyed by irradiation and proper cooking. Discussions of other strategies for control of food-borne toxoplasmosis are available.[3,40]

26.9 # EQUINE PROTOZOAL MYELOENCEPHALITIS

26.9.1 ## Synopsis

26.9.1.1 ### Etiology

Sarcocystis neurona, a protozoa. *Neospora* spp. is an uncommon cause.

26.9.1.2 ### Epidemiology

1522
1523

Sporadic disease occasionally occurring as localized epidemics. Endemic throughout most of the Americas. Disease is infectious but not contagious. The definitive host is the opossum (*Didelphis* spp.).

26.9.1.3 ### Clinical signs

Variable, but commonly asymmetric spinal ataxia, focal, neurogenic muscle atrophy, and/or cranial nerve dysfunction.

26.9.1.4 ### Clinical pathology

No characteristic changes in blood or cerebrospinal fluid. Western blot of blood or CSF has high sensitivity but low specificity.

26.9.1.5 ### Diagnostic confirmation

Histologic demonstration of *S. neurona* in nervous tissue.

26.9.1.6 ### Lesions

Non-suppurative myelo-encephalitis with schizonts and merozoites in neurons, glial cells and leukocytes.

26.9.1.7 ### Treatment

Antiprotozoal agents, including ponazurial, nitazoxanide, or a combination of a sulfonamide and pyrimethamine.

26.9.1.8

Control

Prevent exposure to *S. neurona* by minimizing fecal contamination by opossums of feed. A vaccine is available but not recommended.

26.9.2

ETIOLOGY

The cause is *Sarcocystis neurona*, an ampicomplexan protozoan.[1–3] Isolates of *S. neurona* can vary in their antigenic composition, such that variable responses are observed on immunoblot tests,[4] but the importance of this variation in terms of pathogenicity of the organism is unknown. *Neospora* spp., including *N. hughesi*, cause myeloencephalitis rarely in horses.[5,6]

26.9.3

EPIDEMIOLOGY

Equine protozoal myeloencephalitis (EPM) occurs in horses and ponies in Canada, United States, Central America, and Brazil. Reports of neurological disease in horses with antibodies to *S. neurona* in France have yet to be confirmed, but might represent cases of EPM in native horses outside of the Americas.[7] The disease is reported in other countries in only horses imported from the Americas.[8] Distribution of the disease appears to correlate with the range of the definitive host, *Didelphis virginiana* in North America, or the related species *D. marsupialis* and *D. albiventris* in South America.[9] The disease has not been reported in donkeys and mules. Neurological disease associated with *S. neurona* has been reported in armadillos, sea otters, harbor seals, skunks, raccoons, zebra, lynxes, and cats.[9]

The disease usually occurs sporadically in endemic areas, although epidemics on individual farms are reported.[10] The incidence of EPM is estimated to be 14 new cases per 10 000 horses per year.[11] The **case fatality rate** is approximately 7%, although up to 14% of horses are sold or given away because they are affected by EPM.[11] Approximately 40% of horses recover completely and another 37% improve but do not recover from the disease.[11] Another study reports that only 55% of horses with EPM examined at a referral hospital were alive a minimum of 3 years after diagnosis and treatment.[12]

Seroepidemiological studies, based on detection by Western immunoblot test of multiple antibodies to *S. neurona* in serum,[13] indicates that 45–60% of horses in the United States are exposed to the agent but do not develop disease.[14–17]

Vaccination with a product containing killed *S. neurona* induces a detectable antibody response in both serum and, in approximately 50% of horses, in the cerebrospinal fluid.[18]

26.9.3.1

Risk factors

Risk factors for development of EPM include season of the year, with the highest incidence of new cases being in summer and fall[11,19]; age; use; protection of feed; and presence of opossums on the farm.[19] The disease occurs in horses from 2 months to 19 years of age.[20] Horses <1 year of age are at lower risk of developing disease than are horse 1–4 years of age.[19] Older horses are less likely to develop the disease.[19] Protection of feed from contamination by opossum feces is associated with a decreased risk of disease, whereas presence of opossums on the premises was associated with an increased risk of disease.[19] Horses used primarily for racing and showing are at increased risk of developing EPM with an annual incidence of 38 new cases per 10 000 horses for horses used for racing compared to an incidence of 6 cases per 10 000 horses for horses used for pleasure or farm work.[11] Horses used for showing or competition have the highest annual incidence of 51 cases per 10 000 horses per year.[11] The presence of previous illness is a risk factor for development of EPM.[19] Transportation for 55 hours increases the susceptibility to EPM of horses experimentally infected with *S. neurona*.[21]

26.9.3.2

Transmission

S. neurona is believed to have the two-host life cycle (predator–prey) typical of other *Sarcocystis* and *Toxoplasma* spp. The definitive host is the opossum, *D. virginiana*, and intermediate hosts include raccoons, cats, skunks, sea otter, and armadillo. The domestic cat, 9-banded armadillo, raccoon, and skunk can be infected by ingestion of sporocysts and develop sarcocysts in muscle which when fed to opossums induce shedding of sporocysts,[22–26] thereby confirming the potential for these species to serve as intermediate hosts. Cats living on farms at which EPM has been diagnosed in horses have a higher rate of seroprevalence (40%) than do cats living in a city (10%),[27] providing evidence for a role of cats in the epidemiology of the disease. However, others have detected a lower prevalence of seropositivity (5%) to *S. neurona* among cats in Texas and conclude that cats are not likely to play an important role in the epidemiology of EPM.[28] At least in those areas where raccoons are present they are probably the most important intermediate host.

The definitive host is infected by ingestion of sarcocysts of *S. neurona* encysted in muscle of the intermediate host. The intermediate host is infected by ingestion of sporocysts derived from rupture oocysts passed in the feces of the definitive host. Sporocysts can remain infective in the environment for months, but are probably, based on behavior of other *Sarcocystis* spp. oocysts, killed by drying, high humidity, or freezing and thawing.[29] Birds and insects also serve as transport hosts. Sporocysts ingested by the intermediate host undergo schizogony and ultimately form infective sarcocysts in muscle. Recently, *S. neurona* sarcocysts were detected in muscle of a 4-month-old filly, suggesting that horses might serve as intermediate hosts of the organism.[30] This finding needs to be confirmed as the conventional wisdom is that in horses, *S. neurona* does not complete schizogony and remains as uninfective merozoites in neural tissue.[31] *S. neurona* sarcocysts do not occur in the muscle of horses and horses are therefore not infective to other animals.

There is no evidence of transplacental infection of foals.[32]

The definitive and intermediate hosts of *N. hughesi* have not been determined. Dogs are the definitive host of the closely related *N. caninum*.

26.9.4 PATHOGENESIS

Details of the pathogenesis of EPM are unknown. It is assumed that after infection, probably by ingestion, sporocysts excyst and release sporozoites which penetrate the gastrointestinal tract and enter endothelial cells. Subsequently, meronts (schizonts) develop which on maturation rupture and release merozoites. Schizonts are present in cells of the central nervous system, including neurons, glial cells, and intrathecal macrophages. Schizonts multiply in the infected cells, as evidenced by the presence of merozoites. Infection induces a non-suppurative inflammation, characterized by accumulations of lymphocytes, neutrophils, eosinophils, and gitter cells. Infection of neurons, and the associated inflammatory reaction, disrupt normal nervous function and contribute to the clinical signs of weakness, muscle atrophy, and deficits in proprioception.

1523

1524

Mechanisms permitting infection and proliferation of the organism have not been well defined. Horses with EPM have lesser cell-mediated immunity than do asymptomatic horses,[33] and the decrease in cell mediated immunity appears to be due to *S. neurona* suppressing immune responses to parasite-derived antigens.[34,35] However, foals with severe combined immunodeficiency administered *S. neurona* do not develop neurologic disease, despite prolonged parasitemia and infection of visceral organs by the organism, whereas

immunocompetent horses do not have prolonged parasitemia but do develop neurologic disease.[36,37]

26.9.5 CLINICAL FINDINGS

The incubation period after experimental infection of young horses ranges between 28 and 42 days,[3] but is not known for the spontaneous disease. The clinical findings of EPM in horses are protean, and in endemic areas EPM should be considered as a diagnosis in any horse with clinical signs referable to the nervous system. *S. neurona* can infect any area of the brain and spinal cord, and may affect more than one site in an individual horse. Clinical signs of EPM range from barely perceptible changes in gait or behavior to recumbency, muscle atrophy, or seizures. The onset of **signs** may be insidious and gradual, or acute and rapidly progressive. Affected horses do not have increased temperature or heart rate, unless complications of the nervous disease occur.

Spinal ataxia, evident as weakness, hypometria or hypermetria, and defects in proprioception are common manifestations of EPM. Multifocal spinal or cervical disease causes all four limbs to be affected, while lesions caudal to the cervical intumescence cause signs in the rear limbs only. Signs of spinal ataxia range from subtle changes in gait which are difficult to differentiate from obscure lameness due to musculoskeletal disease, through obvious spinal ataxia evident as truncal sway, toe dragging, and circumduction of feet, to spontaneous falling and recumbency. **Asymmetry** of clinical signs, in which one limb is affected more than the contralateral limb, is highly suggestive of EPM, as cervical stenotic myelopathy and equine degenerative myelopathy usually cause symmetrical ataxia.

Lesions in the sacral cord cause signs of **cauda equina syndrome**, including tail paresis and urinary and fecal incontinence.

Lesions affecting spinal cord gray matter cause focal, **asymmetric muscle atrophy,** absent reflexes, or focal areas of **sweating**. Muscles frequently affected include the quadriceps, biceps femoris, epaxial muscles, and the supraspinatus/infraspinatus group. Equine protozoal myeloencephalitis can present as a brachial plexus injury evident as radial nerve paralysis.

Cranial nerve disease is a common manifestation of EPM. Common syndromes include:

- **Vestibular disease** (CN VIII), evident as circling, nystagmus, head tilt, and falling toward the affected side

- **Unilateral facial nerve paralysis** (CN VII), evident as ear droop, lack of palpebral or corneal reflex and menace on the affected side, and displacement of the upper lip and nares away from the side of the lesion
- **Dysphagia** (CN IX, X, XII) and persistent dorsal displacement of the soft palate
- **Tongue paralysis** (CN XII)
- **Masseter atrophy** and weakness (CN V)
- **Hypalgesia** (Lack of sensation) of the nostrils and skin of the face (CN V).

EPM may also manifest as changes in personality and behavior, headshaking, and seizures.

26.9.6

CLINICAL PATHOLOGY

There are no characteristic changes in the hemogram or serum biochemical variables. **Diagnosis** has focused on the demonstration of antibodies to *S. neurona* in serum or CSF by western blot, indirect fluorescence testing, or IgM capture ELISA.[13,38–40]

Interpretation of the results of **western blot** analysis of **CSF** for IgG antibodies to *S. neurona* is problematic because of the potential for blood contamination of the sample during collection,[41] and the high sensitivity but low specificity of the test.[13] Blood contamination of the sample is problematic in horses that are seropositive for antibodies to *S. neurona* and in which it is desired to know if antibodies are present in cerebrospinal fluid. Contamination of cerebrospinal fluid with blood can introduce antibodies from serum into the otherwise antibody free cerebrospinal fluid thereby causing a 'false' positive test.[41] Contamination of cerebrospinal fluid with small quantities of blood with high concentrations of antibodies to *S. neurona* might not be detectable using red blood cell counts, albumin quotient, or immunoglobulin index, but could yield a positive result on western blot testing.[41]

The western blot test for detection of antibodies to *S. neurona* is sensitive (87%) but has poor specificity (44–60%).[13] The utility of the test therefore depends on the pretest probability that the horse has EPM. The high sensitivity of the test means that the **positive predictive value** of a positive test in a horse with unequivocal signs of neurologic disease consistent with EPM, and from an area in which the disease is endemic, is very good.[42] However, the positive predictive value of a positive test is very poor in horses with vague, or no, signs of nervous disease, or in horses from areas in which the disease is not endemic.[42] The **negative**

predictive value is good in either instance in that horses that test negative for the presence of antibodies are unlikely to have EPM.[42] A negative result on a western blot analysis of serum or CSF, therefore, virtually eliminates the disease from the potential diagnoses, whereas a positive test in a horse with a high pretest probability of the disease contributes little to confirming the diagnosis. A positive test in a horse with a low probability of having the disease, such as presale testing of a clinically normal horse, does not mean the horse has the disease and is virtually useless in any assessment of the horse.

Foals of seropositive mares acquire antibodies, but not infection, by ingestion of colostrum from the dam.[29] These antibodies can be detected in both serum and cerebrospinal fluid of foals.[29,43] The mean time for foals to become seronegative for antibodies to *S. neurona* is 4.2 months.[29] Detection of antibodies to *S. neurona* in serum or cerebrospinal fluid of foals less than 4–6 months of age, even those with neurologic disease, should be interpreted with caution as the antibodies are likely derived from the dam.

An **indirect fluorescent antibody** test reliably detects antibodies to *S. neurona* in serum and cerebrospinal fluid of infected horses.[33,44] This test has the advantages of providing quantitative results, cheaper to perform, and is more accurate than immunoblots in the detection of antibodies. An IgM capture ELISA detects the presence of IgM antibodies to a *S. neurona* -specific antigen in serum and cerebrospinal fluid of naturally and experimentally infected horses, thereby providing evidence of recent infection.[39] Demonstration of recent infection in a horse with signs of neurologic disease increases the probability that the horse has EPM.

Examination of other variables in CSF is of limited use in the diagnosis of EPM, and measurement of creatine kinase activity in CSF has no diagnostic usefulness.[45] The use of the **albumin quotient** or **IgG index** to detect blood contamination of cerebrospinal fluid, or the intrathecal production of IgG is unreliable and not useful in the diagnosis of EPM.[46]

26.9.7 NECROPSY

Lesions are limited to the spinal cord and brain, with the exception of neurogenic muscle atrophy. Gross lesions of hemorrhage and malacia may be visible in the central nervous system tissue. The lesions are asymmetrical, but may be more frequently encountered in the cervical and lumbar intumescences of the spinal cord. Histological examination reveals multifocal necrosis of the nervous tissue with an accompanying infiltration of macrophages, lymphocytes, neutrophils, and occasional eosinophils. This reaction is predominately non-

suppurative and usually includes a degree of perivascular cuffing. Schizonts or free merozoites may be evident in tissues but are difficult to locate without immunohistochemical stains. The sensitivity of screening for the parasite in hematoxylin and eosin-stained sections of nervous tissue from cases with histologic changes suggestive of EPM was only 20%. The sensitivity improved to 51% when immunohistochemical staining of the tissue was employed.[32] The same interpretative problems encountered when testing antemortem CSF samples apply when the fluid is collected at postmortem. Isolation in cell culture systems is possible but rarely attempted in diagnostic laboratories. PCR tests for these apicomplexan parasites can yield false negatives due to the random distribution of the parasite within CNS tissue.

26.9.7.1

Samples for confirmation of diagnosis

- **Histology** – fixed spinal cord (several levels, including cervical and lumbar intumescences) and half of brain, including the entire brain stem, CN VII in some cases (LM, IHC, PCR).

26.9.7.1.1

DIFFERENTIAL DIAGNOSIS

The clinical diagnosis of EPM should be based on the detection of unequivocal neurological abnormalities consistent with EPM and the detection of antibodies to *S. neurona* in an uncontaminated sample of cerebrospinal fluid or blood.[46] A favorable response to treatment specific for EPM increases the likelihood that the horse has EPM. A definitive diagnosis can only be achieved by necropsy.[46]

- Spinal ataxia: see Table 35.1.
- Cauda equina syndrome: EPM should be differentiated from polyneuritis equi; equine herpesvirus-1 myelopathy; and injection of long-acting anesthetics or alcohol around sacral nerve roots.
- Peripheral nerve lesions: Other causes of focal muscle atrophy, such as brachial plexus injury, damage to the supraspinatus nerve, or disuse atrophy can be differentiated from EPM on history and clinical signs.
- Cranial nerve disease: Signs of vestibular disease, facial or trigeminal nerve dysfunction and dysphagia associated with EPM should be differentiated from:
  - Middle ear infection

- Guttural pouch mycosis
- Arthritis and fracture of the temporohyoid articulation
- Head trauma.

26.9.8 TREATMENT

Specific treatment of EPM involves the administration of **antiprotozoal drugs** including ponazuril, diclazuril, nitazoxanide, or the combination of pyrimethamine and sulfadiazine. **Ponazuril**, an active metabolite of toltrazuril, is usually administered at a dosage of 5 mg/kg body weight orally once daily for 28 days. At this dosage, and at 10 mg/kg orally once daily for 28 days, administration of the drug results in resolution of clinical signs in approximately 60% of horses with EPM.[47] The initial dosage is 5 mg/kg q 24 h which is continued for 28 days if signs of improvement are evident after 14 days. If signs of improvement are not seen after 14 days, the dosage is increased to 10 mg/kg orally q 24 for 14 days.[48] Few adverse effects are noted, even at 30 mg/kg orally once daily for 28 days.[49]

Nitazoxanide is administered at 25 mg/kg bodyweight orally for the first 5 days of treatment and then at 50 mg/kg orally for days 6–28 of treatment. Adverse effects noted include fever, anorexia, diarrhea, and worsening of clinical signs of neurologic disease.[50] Nitazoxanide is apparently effective in the treatment of EPM, based on a study of seven horses with the disease, but there are no reports of treatment of large numbers of horses.[50]

Administration of the combination of sulfadiazine (or similar drug, 20 mg/kg, PO) and pyrimethamine (1–2 mg/kg, PO) every 24 hours given 1 hour before feeding is effective in approximately 60–70% of cases.[9] This treatment is continued for at least 90 days if complete resolution of clinical abnormalities occurs, or longer if the signs of EPM do not resolve. **Side-effects** of the administration of a combination of a sulfonamide and pyrimethamine include enterocolitis, anemia, and abortion.[10] Folic acid is often added to the diet of horses being treated for EPM, but this cannot be recommended because of its lack of efficacy in preventing anemia in treated horses,[10,51] and its ability to cause severe congenital abnormalities in foals born to treated mares[52] and anemia and leucopenia in adult horses.[51] Orally administered synthetic folates interfere with normal folate metabolism in horses being administered anti-folate drugs resulting, paradoxically, in folate deficiency.[51] Adequate

intake of folates in antiprotozoal-treated horses can be assured by feeding a diet containing good quality green foliage.

The decision to **stop treatment** in horses that do not completely recover is difficult. Some authorities recommend resampling CSF and continuing treatment until antibodies to *S. neurona* are no longer detectable. However, given that normal horses often have antibodies in their CSF, and that some treated horses never lose their positive western blot test, the decision to stop treatment should not be based entirely on this variable.

Some horses have a transient worsening of clinical signs in the first week of treatment. This is presumed to be due to the effect of the antiprotozoal agent causing death of protozoa with subsequent inflammation and further impairment of neurologic function. Relapse of the disease occurs in some horses when administration of antiprotozoal medication is stopped.

Supportive treatment of affected horses includes anti-inflammatory drugs (flunixin meglumine, 1 mg/kg IV, every 8–12 h; dimethyl sulfoxide, 1 g/kg as a 10% solution in isotonic saline IV, every 24 h for 3 days) and nutritional support for horses that cannot eat. Flunixin meglumine is often administered twice daily for the first 3–5 days of treatment with ponazuril or nitazoxanide, purportedly to reduce the inflammatory effects of death of protozoa in the central nervous system.

26.9.9

CONTROL

A vaccine composed of killed *S. neurona* is available in the United States. However, the efficacy of this vaccine has not been demonstrated. Furthermore, because the vaccine induces detectable antibody in serum and cerebrospinal fluid of vaccinated horses, there is concern that it can impair the diagnosis of EPM.[18] Given the lack of demonstrated efficacy and potential for interference with diagnosis of EPM, use of the vaccine currently available in the United States (2005) is not recommended.

Sporocysts of *S. neurona* are resistant to usual concentrations of many of the conventional disinfectants including sodium hypochlorite (bleach), 2% chlorhexidine, 1% betadine, 5% benzyl chlorophenol, 13% phenol, 6% benzyl ammonium chloride, and 10% formalin.[53] The organism is killed by heating to 55°C for 15 min or 60°C for one minute.[53]

Because protection of feed from contamination by opossums has been demonstrated to reduce the risk of horses developing EPM[19] it is prudent to employ measures to reduce the

exposure of animals and feed to opossum feces, and possibly feces of birds that might act as transport hosts.

There is interest in pharmacologic means of preventing infection of horses by *S. neurona*. Pyrantel pamoate has some efficacy against *S. neurona* in vitro but daily administration (2.6 mg/kg body weight in feed) does not prevent *S. neurona* infection of horses.[54]

26.10 THEILERIOSES

Theilerioses are those tick-borne protozoan diseases associated with *Theileria* spp. in cattle, sheep, and goats as well as in wild and captive ungulates. The genus *Theileria* belongs to the Amplicomplexa group which includes *Babesia, Toxoplasma, Neospora*, *Plasmodium*, among others. The life cycle of *Theileria* spp. involves cyclical development in ticks to form sporozoites which, on being injected with tick saliva into the mammalian host, develop into schizonts in leukocytes and then piroplasms (merozoites) in erythrocytes. The diseases in ruminants are characterized by fever and lymphoproliferative disorders and are associated with varying degrees of leukopenia and/or anemia.

Theileria spp. are found throughout the world and their nomenclature and classification, though still controversial, are being gradually elucidated through molecular characterization. The important pathogens of cattle are restricted to certain geographical regions after which the diseases are named[1–3] (Table 26.6). **East coast fever** (ECF) associated with *T. parva* and **tropical theileriosis** (**or Mediterranean coast fever**) associated with *T. annulata* are the most important and are dealt with separately below. Japanese bovine theileriosis associated with *T. sergenti* is probably next in importance.

T. orientalis is responsible for **oriental theileriosis**, a milder disease than ECF or bovine tropical theileriosis, and hence also called **benign theileriosis**. It has been proposed that the species found worldwide and responsible for benign theileriosis be named *T. buffeli* (replacing *T. orientalis* in Asia and *T. sergenti* in Japan[1]) but genetic differences have been shown between *T. buffeli* and *T. sergenti*.[4,5] Furthermore, *T. sergenti* causes a more severe disease in southeastern Asia, also called Japanese bovine theileriosis. Both *T. buffeli* and *T. sergenti* are

transmitted by *Haemophysalis* ticks which occur in Europe, the Mediterranean basin, Asia, and Australia. Although this tick does not occur in the United States of America, *T. buffeli* was diagnosed in a herd of beef cattle in Missouri and was associated with severe clinical illness and death (by euthanasia) in a pregnant cow.[6]

In general, benign theileriosis is characterized by moderate to severe anemia in heavily parasitized cattle and moderate enlargement of lymph nodes. More severe clinical signs and economic losses have been reported from eastern Asia. The pathogenesis of the anemia is not clear but a hemolytic factor has been reported in the serum of acutely affected cattle.[7] In addition, it has been shown that oxidative bursts of macrophages in experimentally infected cattle can damage red blood cells and that this may contribute to the anemia in Japanese bovine theileriosis.[8] European breeds are more susceptible than zebu breeds. Even for the more pathogenic *T. sergenti*, native and crossbred cattle in Korea were found to be more resistant to infection than Holsteins.[9] Furthermore, transplacental (vertical) transmission of *T. sergenti* from pregnant cows to calves has been reported.[10] Transmission to the calves was confirmed by parasitological, serological, and polymerase chain reaction (PCR) assays. These are also the methods generally recommended for diagnosis.[5] Calves used for the production of live vaccines against babesiosis and anaplasmosis should be free of benign theileriosis. In Australia, concurrent treatment with primaquine phosphate (six doses at 2 mg/kg) and halofuginone lactate (two doses at 1 mg/kg) was effective for this purpose.[11]

T. mutans, confined to Africa and the Caribbean Islands, causes a usually innocuous disease, but it may be manifested by fever, anorexia, and anemia. Another species, *T. velifera*, is associated with very mild theileriosis in tropical Africa. Both are transmitted by *Amblyomma* ticks. *T. taurotragi* of the eland antelope is generally non-pathogenic to cattle, but is one of the causes of **cerebral theileriosis** (**turning sickness**) in southern Africa (cerebral theileriosis can also be associated with *T. parva*). Parasitized lymphoblasts accumulate in cerebral, spinal, and meningeal arteries, with resultant thrombosis and infarction of affected organs. *T. taurotragi* is transmitted by *Rhipicephalus* spp.

The important pathogen of sheep and goats is *T. hirci* (synonym *T. lestoquardi*), the cause of **malignant ovine theileriosis**. The disease is enzootic from North Africa through the Middle East to India and China, approximately the same geographical region as bovine tropical theileriosis. Malignant theileriosis in sheep and goats is similar to bovine tropical theileriosis due to *T. annulata*. Like the latter, it is also transmitted by *Hyalomma* spp. but in China, the main vector is *Haemophysalis* spp. The disease can be acute, subacute, or chronic, depending on the resistance of the sheep or goats, and is seasonal, depending on availability of ticks. The

acute disease is characterized by fever and very high mortality in 3–6 days.[12,13] Anemia, jaundice, and enlargement of lymph nodes are characteristic, and both piroplasms and schizonts can be demonstrated in smears of blood and tissues, respectively. In subacute and chronic cases, signs are generally less marked except for anemia and emaciation. An indirect fluorescent antibody test is available. Parvaquone and buparvaquone may be used to treat early cases. **Benign ovine theileriosis** is caused either by *T. ovis* or by *T. separata* in Africa. Piroplasms are found in blood but there are no overt clinical signs.

Table 26.6 Summary of the theilerioses of domestic ruminants[1–3]

Disease	Distribution	*Theileria*. spp.	Main vector
Cattle			
East coast fever	East and central Africa	*T. parva*	*Rhipicephalus appendiculatus*
Turning sickness (cerebral theileriosis)	Southern Africa	*T. parva, T. taurotragi*	*Rhipicephalus* spp.
Tropical theileriosis (Mediterranean coast fever)	Mediterranean countries Indo-China	*T. annulata*	*Hyalomma anatolicum*
Benign theileriosis	Worldwide Africa/ Caribbean	*T. buffeli (T. sergenti, T. orientalis)*	*Haemophysalis* spp.
		T. mutans	*Amblyomma* spp.
Japanese bovine theileriosis	Africa	*T. velifera*	*Amblyomma* spp.
	Asia	*T. buffeli*	*Haemophysalis*
	Japan	*T. sergenti*	*longicornis/H. punctata Haemophysalis* spp.
Sheep and goats			
Malignant ovine theileriosis	North Africa, Middle East, India Worldwide	*T. hirci (T. lestoquardi)*	*Hyalomma* spp./ *Haemophysalis* spp.*?*
		T. ovis	*Rhipicephalus* spp.*?*
Benign theileriosis	East and South Africa	*T. separata*	*Rhipicephalus* spp.

In general, the pathogenesis of various forms of theileriosis is dependent on the production of schizonts in lymphocytes and piroplasms in erythrocytes. Thus, *T. parva*, *T. annulata*, and *T. hirci* produce numerous schizonts and piroplasms and are very pathogenic; *T. mutans*, *T. buffeli*, and *T. ovis* rarely produce schizonts but may cause varying degrees of anemia when

piroplasms are many in red blood cells; and with *T. velifera* and *T. separata*, no schizonts have been described, the parasitemia is usually scanty and the infection is mild or subclinical.

26.11 EAST COAST FEVER (ECF)

26.11.1 Synopsis

26.11.1.1 Etiology

Theileria parva, an apicomplex protozoon. Vector is *Rhipicephalus appendiculatus* and, rarely, *R. zambeziensis*.

26.11.1.2 Epidemiology

Endemic disease of cattle in east and central Africa; high mortality and great economic importance.

26.11.1.3 Pathogenesis

Tick inoculation of sporozoites → lymphocytes in local lymph node → schizogony → lymphoid proliferation → parasitemia → more lymphoid proliferation → merozoites → erythrocytes → piroplasms → ticks. Damage mainly by schizonts.

26.11.1.4 Clinical signs

Fever, enlarged superficial lymph nodes, dyspnea, wasting, and terminal diarrhea.

26.11.1.5 Clinical pathology

Schizonts in lymphoblasts, piroplasms in erythrocytes, serology.

26.11.1.6 Lesions

Massive pulmonary edema, hydrothorax, hydropericardium, emaciation, hemorrhages, lymphadenopathy, and widespread proliferation of lymphoblastoid cells.

26.11.1.6.1 Differential diagnosis list

- Trypanosomosis/babesiosis/anaplasmosis
- Heartwater
- Malignant catarrhal fever/bovine virus diarrhea/Rinderpest.

26.11.1.6.2 Treatment

Limited success with halofuginone, parvoquone, and tetracyclines.

26.11.1.6.3 Control

Integrated approach involving resistant animal breeds, strategic application of acaricides, and vaccination by infection-and-treatment methods.

26.11.2 ETIOLOGY

Theileria parva is an apicomplex protozoan parasite of the class Sporozoasida and order Piroplasmida. There has been considerable naming and renaming of *T. parva* and the associated diseases in Africa.[1] 'Classic' East Coast Fever (ECF) occurs in East Africa and is

associated with *T. parva* transmitted from cattle to cattle by the brown ear tick, *Rhipicephalus appendiculatus*. ECF also occurs either as *Corridor disease* in eastern and southern Africa or as **January disease** in central Africa. Corridor disease is transmitted from buffalo to cattle by either *R. appendiculatus* or *R. zambeziensis* and the agent responsible used to be called *T. parva lawrencei*. Close contact between buffalo, cattle, and ticks is essential. The disease is more acute than classical ECF, but after serial passage in cattle, it is indistinguishable from classical ECF.[2] January disease occurs mainly between January and March and the agent was named *T. parva bovis*. The disease is also more acute than classical ECF, death sometimes occurring within 4 days. These three clinical diseases are otherwise indistinguishable from one another, hence the causative agents are currently referred to simply as *T. parva*.

26.11.3 EPIDEMIOLOGY

26.11.3.1 Occurrence

ECF affects mainly cattle but also buffalo, and occurs in 13 countries in eastern, central, and southern Africa.[3] Its occurrence is related to the distribution of the vector tick which has been recorded from large areas extending from southern Sudan in the north to western Zambia and eastern Zaire in the west, and to Mozambique and Zimbabwe in the south.[4,5] The disease is prevalent throughout the wetter areas favoring the development of the tick, but is absent from the wet highlands in the horn of Africa.[6] It has been eradicated from southern Africa up to the Zambezi River. The endemic scenerios range from a stable situation with high prevalence of herd infection but low fatality rates (endemic stability), to a low prevalence/high fatality scenerio (endemic instability).[7] Endemic stability develops in indigenous zebu cattle exposed to constant tick challenge as in wetter areas whereas endemic instability is seen with commercial production systems utilizing imported breeds or crossbreeds and in areas with a unimodal rainfall pattern that restricts tick activity.[8] Epidemics occur when there is a breakdown in tick control especially during the rainy season or when susceptible animals are introduced into an endemic area.

26.11.3.2 Morbidity and case fatality

1527
1528

All susceptible cattle in endemic areas are at the risk of contracting ECF unless they are vaccinated or the tick population is under stringent control. The morbidity and case fatality rates are very high, approaching 90–100% in recently introduced exotic (*Bos taurus*)

breeds and in previously unexposed or naive indigenous cattle.[9] However, indigenous zebu cattle (*Bos indicus*) and African buffalo in endemic areas have a strong resistance to the disease and calfhood mortality is around 5%.[9]

26.11.3.3

Methods of transmission

The vector of ECF is *Rhipicephalus appendiculatus* and in the field, the disease occurs only where this tick is found, except for Corridor disease which may be transmitted by *R. zambeziensis*. Other species of *Rhipicephalus* and *Hyalomma* spp. can transmit ECF experimentally, but they are not significant. Developmental stages of the parasite occur in the tick and they pass trans-stadially through the stages of larva, nymph and adult, but there is no transovarian transmission. Consequently, larvae or nymphs become infected and transmit infection as nymphs or adults. Adults are more efficient vectors than nymphs. Mechanical transmission is of no significance. The epidemiology of the disease is thus largely dependent on the distribution and habitat of the tick and its ability to complete development to the adult stage, usually during the rainy season. Ticks may live for 1–2 years, but they lose their infection within 11 months.

26.11.3.4

Risk factors

The most important risk factors relate to the presence of the brown ear tick in a given area and the level of tick burden per animal, even though it takes only one tick to establish an infection that could be fatal. At low infestation rates, an average of five ticks per head (two to three per ear) will sustain endemicity; one to four per head will invite epidemicity; while an average of less than one can allow sporadic outbreaks.[10] In addition, there is evidence that *R. appendiculatus* populations that originate from eastern Africa tend to become more highly infected with *T. parva* than those that originate from southern Africa, and consequently the disease they transmit is more virulent.[11]

The infection rate in ticks in endemic areas is usually low (1–2%) even though the immunity conferred on recovered or vaccinated animals is no longer thought to be sterile. However, soon after ECF becomes established in susceptible herds, infection rates in ticks become much higher.

Young animals are less susceptible, and indigenous breeds and buffaloes are less clinically affected than exotic breeds, but buffaloes are the carriers of Corridor disease. Other wild

Bovidae may help to sustain the population of the tick vector but are not carriers of *T. parva*. Asiatic or water buffalo is fully susceptible.

26.11.3.4.1

Environmental factors

In eastern Africa, *R. appendiculatus* normally occurs in grass-covered savannah and savannah woodlands, but is usually absent from extensive heavily wooded forest habitats.[5] Areas that are too high, too cold, or too dry will not allow the tick to undergo more than one life cycle in a year, thereby reducing the period of transmission of theilerial parasites by the nymphs or adults. For example, the disease is most prevalent in eastern Africa where adult and immature stages of the tick occur simultaneously on cattle, leading to rapid and continuous transmission.[11] In southern Africa, by contrast, there is a seasonal life cycle for the tick so that there is little overlap between the activity periods of adults (January to March) and immature stages, thereby reducing the frequency of disease transmission.

26.11.3.5

Immune mechanisms

Cattle recovering from ECF have a solid immunity to homologous challenge, but the immunity is not sterile. In endemic areas, premunity is established early and this provides lifelong protection if reinfection continues and the cattle are not moved to a different location where they may be exposed to a different strain of the parasite. Indigenous cattle are able to limit explosive multiplication of schizonts during the acute phase.[12] Nutritional or climatic stress may seriously reduce the animal's premunity, even among resistant breeds. While antibody responses to the sporozoite may play some part in protection, immunity is mediated mainly by cellular mechanisms involving cell-mediated cytotoxic T-cell (CTL) responses against surface antigens of macroschizont-infected cells.[13] The CTL response is parasite-specific and genetically restricted (major histocompatibility complex or MHC antigens) and the protection can be transferred between immune and naïve calves in the $CD8^+$ T-cell fraction emanating from a responding lymph node.[7]

26.11.3.6

Experimental reproduction

ECF can easily be reproduced by feeding infected ticks on susceptible cattle or by inoculating cattle with infected tick material, sporozoites or macroschizont-infected tissue culture cells. This is used as a method of immunization. When working with ticks or tick materials, care should be taken to avoid the risk of contracting other tick-borne diseases.

26.11.3.7 Economic importance

ECF has a major impact on cattle production in eastern, central, and southern Africa. It is estimated that in 1989, ECF killed 1.1 million head of cattle and caused US$168 million in losses.[14] Serious losses occur in exotic and indigenous cattle, mainly from reduced production of milk and meat due to morbidity and mortality, as well as from the heavy costs incurred in implementing effective tick control. *T. parva* does not infect human beings.

26.11.3.8 Biosecurity concerns

The vector of ECF has strict requirements which limit the spread and establishment of the disease beyond the geographic areas where it normally occurs. It is not contagious.

26.11.4 PATHOGENESIS

Sporozoites of *T. parva* are injected into the bovine host by the tick in its saliva. Ticks must feed for 2–4 days before sporozoites in their salivary glands will mature and become infective to cattle. One tick can transmit sufficient sporozoites to cause a fatal infection in a susceptible animal. The sporozoites then enter lymphocytes and develop into schizonts in the lymph node draining the area of attachment of the tick, usually the parotid node. Infected lymphocytes are transformed to lymphoblasts which continue to divide synchronously with the schizonts so that each daughter cell is also infected. Eventually, infected lymphoblasts are disseminated throughout the lymphoid system and in nonlymphoid organs where they continue to proliferate. Later, some schizonts differentiate into merozoites, are released from the lymphoblasts and invade erythrocytes where they are referred to as piroplasms and are infective to ticks. Piroplasms ingested by ticks undergo several developmental stages and eventually form sporozoites in salivary glands, thus completing the cycle.

The dominating pathological lesion is generalized lymphoid proliferation resulting from uncontrolled proliferation of T-lymphocytes containing schizonts. This is followed later by necrosis of infected lymphoblasts induced by cytotoxic T-lymphocytes. The severe lymphocytolysis often leads to immunosuppression. Terminally, the animal develops severe pulmonary edema, probably due to release of vasoactive substances from lymphocytes disintegrating in the lungs. Erythrocytic indices are usually unchanged, but there may be terminal anemia in January disease.

26.11.5 CLINICAL FINDINGS

The basic syndrome associated with *T. parva* infection lasts for a few weeks. The incubation period is 1–3 weeks, depending on the virulence of the strain and the size of the infecting dose. Experimentally, the first clinical sign is enlargement of lymph nodes in the area draining the site of tick attachment (i.e. 8–16 days after attachment). One or 2 days later, there is fever, depression, anorexia, and a drop in milk in dairy animals. In later stages, there may be nasal and ocular discharges, dyspnea, generalized lymph node enlargement, and splenomegaly. In severe cases, diarrhea occurs, sometimes with dysentery, but usually only late in the course of the disease. Emaciation, weakness, and recumbency lead to death from asphyxia in 7–10 days. Terminally, there is often a frothy nasal discharge. Occasional cases of brain involvement occur and are characterized by circling, hence ‘turning sickness’ or cerebral theileriosis.

1528 1529

In southern Africa, cerebral theileriosis is associated with an aberrant form of *T. taurotragi* originating from the eland. There are localized nervous signs and convulsions, tremor, profuse salivation, and head pressing. Infection with the strain of *T. parva* (formerly *T. parva lawrencei*) responsible for Corridor disease causes a similar acute syndrome, with the additional lesion of keratitis and accompanying blepharospasm. ECF in Zimbabwe (formerly attributed to *T. parva bovis*) is generally slightly less virulent but is still frequently fatal.

26.11.6 CLINICAL PATHOLOGY

The parasites are evident as schizonts, sometimes in circulating lymphocytes, but mainly in biopsy smears of enlarged lymph nodes stained with Giemsa. Piroplasms are also easily visible in erythrocytes from day 16 after tick attachment and they increase in number until death. Over 30% of the red cells may be infected, but the level of intra-erythrocytic piroplasms is not correlated with the severity of the disease. *T. parva* piroplasms are difficult to differentiate from other piroplasms, hence the necessity to find schizonts. Blood counts will reveal a panleukopenia and thrombocytopenia with little or no anemia. The protozoa can be grown on a tissue culture of lymphoblastoid cells.

A range of serological tests is available, including indirect immunofluorescent antibody test (IFAT), complement fixation test, indirect hemagglutination test, and enzyme-linked immunosorbent assay (ELISA). The ELISA test is increasingly being used for seroepidemiological studies[14] and the polymerase chain reaction (PCR) technology is available but IFAT is the most widely used test.[3]

26.11.7 NECROPSY FINDINGS

The most striking lesion is massive pulmonary edema, hyperemia and emphysema, along with hydrothorax and hydropericardium. Copious froth is present in the airways. The carcass is emaciated and hemorrhages are evident in a variety of tissues and organs. There is enlargement of the liver, lymph nodes and spleen, and ulceration of abomasum and intestines. Small lymphoid nodules (the so-called pseudo-infarcts) are present in liver, kidney, and alimentary track. In protracted cases, animals may have small, exhausted lymphoid organs.

Microscopic lesions are characterized by proliferating lymphoblastoid cells and varying amounts of necrosis in lymphoid organs, lungs, liver, kidneys, the gastrointestinal tract and other tissues, somewhat similar to a multicentric lymphoid tumor. Some lymphoblasts contain schizonts, which are better seen in impression smears stained with Giemsa stain. In cerebral theileriosis, infected lymphoblasts sequester in cerebral blood vessels and cause infarction.

Specimens to submit for pathology should include lymph nodes, lungs, kidneys, liver, and any other organ with gross lesions.

26.11.7.1 DIFFERENTIAL DIAGNOSIS

The fever, depression, and lymphadenopathy of ECF can be confused with such diseases as theileriosis due to *T. annulata*, trypanosomosis, heartwater, malignant catarrhal fever, bovine virus diarrhea, and rinderpest. The lympoid hyperplasia may also simulate lymphoma. A knowledge of the disease history, coupled with hematological and lymph node smear examinations are usually adequate to make a definitive diagnosis.

26.11.8 TREATMENT

Once an animal is manifesting clinical signs of ECF, treatment is generally considered to be either unsatisfactory or too expensive.[15] Tetracyclines were the recommended treatment for many years, but they have only moderate efficacy, especially if the disease has been present for a few days. Two recently introduced drugs, halofuginone lactate and parvaquone, have had a much higher success rate, but recovered animals may become carriers unless the correct dose is used. Halofuginone lactate is an effective oral treatment for the acute syndrome at two doses, 1.2 mg/kg BW. Parvaquone (10 mg/kg BW, two doses 48 h apart) or

the related buparvaquone (2.5 mg/kg BW, two doses 48 h apart) given IM is effective in most cases. In field trials, buparvaquone gives results comparable to those of parvaquone[16] and cure rates are maximized by accurate diagnosis and prompt treatment of both ECF and intercurrent infections.[17] Cure rates are even higher if the animals are also treated for pulmonary edema with dexamethasone[18] or the diuretic, frusemide.[19,20]

26.11.9 CONTROL

Until recently, the main method of control of ECF was to break the transmission cycle between cattle and ticks. This was achieved through widespread and strict application of acaricides at 3-, 5-, or 7-day intervals throughout the year (intensive dipping), adherence to legislation on cattle movements and quarantine, and good livestock and pasture management. With the ever rising costs of acaricides, their effect on the environment, the development of acaricide resistance, and frequent political problems in the affected regions, this strategy to control ECF and other tick-borne diseases in Africa has been revised.[21–23] Furthermore, it has been observed that indigenous cattle, constituting the majority of the herds in some of the affected countries, may lose their endemic stability with intensive dipping[24] and the process is not cost-effective. An integrated approach is now advocated involving the use of genetically resistant breeds, a judicious and selective application of acaricides at 3-week intervals (strategic dipping) or when there are at least 100 ticks per animal (tactical dipping), and the use of vaccines. It was reported that monthly applications of deltamethrin-based pour-on insecticide significantly reduced the incidence of ECF and other hemoparasitic diseases in smallholder dairy farms in Kenya.[25]

The technique used for vaccination is immunotherapy or ‘infection-and-treatment method’. Initially, cryopreserved suspensions of *T. parva* sporozoites from ground-up infected ticks were injected into the patient. Now, sporozoites from cell culture are used. The infection they cause is controlled with long-acting oxytetracycline (20 mg/kg BW IM), or preferably parvaquone given at the same time, so that premunity is established. It is preferably to use a cocktail of different stocks of parasites. Vaccination, coupled with strategic dipping only when ticks are abundant, is usually successful and economically attractive,[23] provided local stocks of *Theileria* are included. Large-scale field trials of these vaccines are being carried out throughout East and Central Africa. Initial reports indicate that calves in high risk areas should be vaccinated at 1–2 months of age[26]; that immunization campaigns are more efficient when concentrated in the period of low adult tick activity[27]; and that immunization is of no benefit in herds under intensive tick control but is of high value when combined with

1529 1530

strategic tick control.[28] Strategic control plus immunization can markedly reduce the risk of clinical ECF but immunized animals are carriers and all stages of *R. appendiculatus* can transmit infection from them to naïve animals.[29]

Limited studies have indicated that cattle could be successfully immunized without concurrent tetracycline therapy by using low pathogenicity isolates as vaccines, for example, *T. parva* (Boleni),[30] or low infectivity sporozoite stabilates stored at – 196°C for over 6 months.[31] Because of the high cost of tetracyclines, this procedure would reduce the cost of vaccination by more than three-fold in the first year of field application. Furthermore, the *T. parva* (Boleni) isolate was reported to induce protection against a wide spectrum of *Theileria* stocks.

It needs to be stated that immunity is engendered so far only with live parasites that can establish an infection, but can also produce carriers. Hence, the risk inherent in the widespread use of such vaccines across national boundaries warrants further consideration. On the other hand, this process may accelerate progress to endemicity.[32] The possibility of immunizing cattle with recombinant surface molecules from either the sporozoite (the p67 antigen) or the schizont, or a mixture of several antigens derived from both stages, is still being investigated.[33,34] Such a recombinant vaccine would avoid the breakdowns that occur with any immunotherapeutic technique and if the right antigens are found for the vaccine, the immunity engendered is likely to be broad, robust, and not parasite stock-specific.[33,35,36]

26.12 TROPICAL THEILERIOSIS (MEDITERRANEAN COAST FEVER)

26.12.1 Synopsis

26.12.1.1 Etiology

Theileria annulata, an apicomplex protozoon. Vectors are *Hyalomma* ticks.

26.12.1.2 Epidemiology

Endemic disease of cattle in Mediterranean basin and parts of Asia.

26.12.1.3 Pathogenesis

As in ECF, but damage is by both schizonts and piroplasms.

26.12.1.4 Clinical signs

Inapparent in local stock; fever, lymphadenopathy, wasting, anemia, and jaundice in exotics.

26.12.1.5 Clinical pathology

Schizonts in macrophages and lymphocytes especially in liver smears; piroplasms in erythrocytes.

26.12.1.6 Lesions

As in ECF, also anemia and jaundice.

26.12.1.6.1 Differential diagnosis list

- Other theilerioses
- Babesiosis
- Anaplasmosis
- Trypanosomosis
- Malignant catarrhal fever.

26.12.1.6.2 Treatment

Buparvaquone is effective.

26.12.1.6.3 Control

None required for indigenous cattle; vaccination and strategic tick control for exotics.

26.12.2 ETIOLOGY

Theileria annulata is a member of the apicomplex group, like *T. parva* the cause of east coast fever. It is highly virulent for European dairy cattle. Infection in local zebu cattle is often subclinical.

26.12.3 EPIDEMIOLOGY

26.12.3.1 Occurrence and methods of transmission

The disease occurs from Morocco and Portugal in the west through the Mediterranean basin and the Middle East to India and China in the east. *T. annulata* affects cattle and is transmitted trans-stadially by the three-host tick *Hyalomma anatolicum* in central-western Asia and north-eastern Africa, and by the two-host tick *H. detritum* in the Mediterranean basin. The extent of its distribution may overlap with that of *T. parva* in Sudan and Eritrea and with *T. sergenti* in the Far East. In endemic areas, virtually all adult animals are

infected, but case fatality is about 10–20% and is confined mainly to calves. Exotic animals recently introduced may have 20–90% mortality. The disease occurs when there is much tick activity, mainly in summer and the rainy seasons, and in crossbred animals. A single tick can cause fatal infection since its salivary glands usually contain numerous sporozoites. An outbreak occurred recently in a Scottish dairy farm and was believed to have been due to mechanical transmission from experimentally infected calves on a research institute associated with the farm. In the absence of natural vectors, that outbreak was quickly controlled.[1]

26.12.3.2 Risk factors and immune mechanisms

The normal state is that of endemic stability. This balance is disturbed when exotic animals are introduced and heavier losses occur. Recovered animals show a solid, long-lasting immunity, but they remain as carriers. Buffaloes are believed to be the natural hosts and may also act as carriers whereas yaks are highly susceptible. As with *T. parva*, immunity is mainly cell-mediated but is poor in calves. Experimental reproduction is by feeding infected ticks on cattle or by needle inoculation of sporozoites in macerated ticks, schizonts in lymphocytes, or merozoites in erythrocytes. Humans are not affected.

26.12.3.3 Economic importance

The disease is a major constraint to livestock improvement programs in many parts of the Middle East and Asia[2] and about 200 million cattle are at risk.[3]

26.12.3.4 Biosecurity concerns

There are none.

26.12.4 PATHOGENESIS

1530

The life cycle of *T. annulata* is cattle-tick-cattle as for *T. parva* but unlike *T. parva*, the sporozoites of *T. annulata* invade and form schizonts mostly in macrophages/monocytes that express major histocompatibility (MHC) class II antigens, rather than in lymphocytes.[4] Schizont infected cells multiply in the draining lymph nodes and disseminate rapidly throughout the lymphoid tissues and in non-lymphoid organs including the liver, kidney, lung, abomasum, and brain. Later, schizonts differentiate into merozoites and invade erythrocytes (as piroplasms). The pathogenesis therefore involves proliferation of lymphocytes and macrophages induced by schizonts and anemia with icterus induced mostly

1531

by the piroplasms. The lymphoproliferation is controlled by suppressor macrophages as a protective mechanism leading to recovery.[5] Over 90% of erythrocytes may be parasitized, each by one or more merozoites. Immunosuppression may occur in the acute phase of lymphoproliferation, but is generally less marked than in ECF,[3] probably because leukocyte numbers return to normal soon after the acute phase.

26.12.5 CLINICAL FINDINGS

In a stable endemic situation, there may be only mild or no clinical disease in local zebu cattle.[4] Clinical signs are acute and severe in exotic cattle and less severe in crossbreeds, and are similar to those in ECF. However, the course is longer in tropical theileriosis and may last for weeks before death. Clinical signs include marked fever, swelling of superficial lymph nodes, inappetence, tachycardia, dyspnea, pale mucous membranes and icterus. Others are diarrhea, weight loss, convulsions, torticollis and other nervous signs.[6,7] In chronic cases, there may be small subcutaneous nodules from which schizonts can be demonstrated in smears.[8]

26.12.6 CLINICAL PATHOLOGY

As with ECF, examination of smears of blood and lymph node biopsy will reveal piroplasms in erythrocytes and schizonts in lymphocytes. Schizonts of *T. annulata* tend to be more common in the liver than in lymph node smears, but are otherwise indistinguishable from those of *T. parva*. Furthermore, the piroplasms are predominantly round and oval, as opposed to *T. parva* which has comma- and rod-shaped piroplasms. Anemia is a significant feature of tropical theileriosis, unlike in ECF, and is associated with bilirubinemia, hemoglobinuria, and bilirubinuria. The anemia results from destruction of erythrocytes containing piroplasms but other factors may include autoimmune hemolysis and poor bone marrow response. Reduction in white cell and platelet counts is less severe than in ECF, but animals dying from the disease show persistent and severe lymphocytopenia involving mainly T-lymphocytes.[6]

The most commonly used serological diagnostic technique is the indirect fluorescent antibody test. For surveys, an indirect enzyme-linked immunosorbent assay (ELISA) test using a recombinant *T. annulata* surface protein has been described.[9] The ELISA tests provide higher sensitivity and specificity than IFAT.[10] Carriers can be detected by the polymerase chain reaction (PCR),[11] a test that can also be used to detect infected ticks.

26.12.7 ## NECROPSY FINDINGS

Apart from pallor of mucous membranes and yellowish discoloration of tissues, the postmortem lesions in animals dying from tropical theileriosis are similar to those of ECF. Liver, spleen and lymph nodes should be submitted for laboratory examination to detect schizonts whereas merozoites are detected in blood smears.

26.12.7.1 ### DIFFERENTIAL DIAGNOSIS

Tropical theileriosis may be confused with the other theilerioses that may occur in the region, and with babesiosis, anaplasmosis, trypanosomosis, and malignant catarrhal fever. Liver biopsy and blood examination will help to confirm a clinical diagnosis.

26.12.8 ## TREATMENT

Buparvaquone is the most effective agent available, and the recommended dose is 2.5 mg/kg BW.[12] In calves, supportive treatment for anemia is indicated. Halofuginone at 1.2 mg/kg is also effective but tetracycline at 20 mg/kg is less so.

26.12.9 ## CONTROL

Indigenous cattle live with the disease and do not require any intensive tick control or treatment. For valuable exotic stock or their crossbreeds, vaccination and strategic tick control are recommended. Vaccines can be made from either the sporozoite or the schizont. The sporozoite vaccine is based on the infection-and-treatment method using schizont-infected cell lines and simultaneous tetracycline treatment as for *T. parva*. It has been suggested that the most economical way to control theileriosis in India is to vaccinate calves and to reserve buparvaquone for treating clinical cases.[13] The schizont vaccine was formerly blood containing a mild strain of the parasite. The newer vaccines are prepared from live schizonts grown in lymphoid cell culture and attenuated by prolonged passage. They cause virtually no adverse reactions and vaccinated cattle show good resistance to the disease for at least 3.5 years. Therefore, it is necessary to revaccinate, preferably with a different cell line vaccine, if tick population is too low to establish endemic stability. The risk for spread of the vaccine strains in the field is very low.[14]

26.13 Diseases associated with trypanosomes (tryponosomoses)

Trypanosomes are flagellated protozoan parasites that live in the blood and other body fluids of vertebrate hosts. With the help of the flagellum, they swim in body fluids, boring their way between cells. They generally possess a kinetoplast and undergo cyclical development in an arthropod vector. Their biological adaptations, morphology, and pathogenicity are fascinating and are being extensively studied. Each of the parasites causes a disease (now termed

trypanosomosis rather than trypanosomiasis) in animals and humans as summarized in Table 26.7. Trypanosomoses of veterinary importance are discussed below.

26.13.1 NAGANA (SAMORE, AFRICAN TRYPANOSOMOSIS, TSETSE FLY DISEASE)

26.13.1.1 ETIOLOGY

Trypanosoma vivax, T. congolense, T. brucei brucei and *T. simiae* are the four main species responsible for African trypanosomoses affecting virtually all domestic mammals. *T. vivax* and *T. congolense* are the main pathogens of cattle. The four species are members 1531
of the *Salivaria* group of trypanosomes and are transmitted cyclically via the mouthparts of 1532
tsetse flies, hence the name salivarian trypanosomes. *T. vivax* is usually numerous in bovine blood, and can be identified by its very fast movement in wet films. In stained smears, it is a long, slender, monomorphic parasite with a rounded posterior end, a terminal kinetoplast, and a long free flagellum, but no prominent undulating membrane. *T. congolense* is smaller, sluggish in wet films, and often adheres to red blood cells by the anterior end. In stained smears, it is a short parasite with a marginal kinetoplast, no free flagellum, and no prominent undulating membrane. *T. brucei* is large like *T. vivax*, but its rapid movement is in confined areas of the wet film. In stained smears, it is pleomorphic and may occur as long and slender forms, intermediate forms, or short and stumpy forms. The slender and intermediate forms have a long free flagellum, pointed posterior end, subterminal kinetoplast and a prominent undulating membrane, whereas the stumpy forms resemble *T. congolense*, but are bigger and have a prominent undulating membrane. *T. simiae* is morphologically indistinguishable from *T. congolense*, but the organism will be swarming in the blood of pigs.

Table 26.7 Summary of the trypanosomoses of domestic animals and humans

Disease	Distribution	*Trypanosoma* spp.	Main vector
Animals			
Nagana or African trypanosomosis (most mammals)	Tropical Africa	*T. brucei brucei*	*Glossina* spp.
		T. congolense	Other biting flies
		T. vivax	
		T. simiae	
Surra (horses, camels, buffaloes)	Africa, Asia, South and Central America	*T. evansi*	Biting flies
Dourine (horses and donkeys)	Africa, Asia, South and Central America	*T. equiperdum*	None (venereal transmission)
Non-pathogenic (cattle and sheep)	Worldwide	*T. theileri*	
		T. melophagium	Biting flies
Humans			
Rhodesian sleeping sickness	East, central and southern Africa	*T. brucei rhodesiense*	*Glossina* spp.
Gambian sleeping sickness	West and central Africa	*T. brucei gambiense*	*Glossina* spp.
Chagas' disease (also in dogs, cats and pigs)	South and Central America, southern United States	*T. cruzi*	*Rhodnius* spp.
			Triatoma spp.

26.13.1.1.1

Synopsis

26.13.1.1.1.1

Etiology

Trypanosoma congolense, T. vivax, T. brucei and T. simiae, all salivarian trypanosomes. Parasites undergo cyclical development in tsetse flies (*Glossina* spp.), the vector, but they can also be transmitted mechanically by other biting flies.

26.13.1.1.1.2

Epidemiology

Endemic disease of all mammals in tropical Africa, also Central and South America; of greatest economic importance in cattle.

26.13.1.1.1.3

Pathogenesis

Fly inoculation of metacyclic trypanosomes → chancre → trypomastigotes → intermittent parasitemia → anemia with or without tissue invasion → other clinical signs and immunosuppression.

26.13.1.1.1.4

Clinical signs

Fever, apathy, pale mucous membranes, swollen lymph nodes, progressive emaciation, cachexia and death. May be acute, subacute or, often, chronic.

26.13.1.1.1.5

Clinical pathology

Progressive anemia, parasite detection in blood by various methods.

26.13.1.1.1.6

Lesions

Not definitive but include palor, emaciation, enlargement of liver, spleen and lymph nodes.

26.13.1.1.1.6.1

Differential diagnosis list

- Malnutrition
- Helminthosis
- East coast fever
- Babesiosis
- Anaplasmosis
- Hemorrhagic septicemia.

26.13.1.1.1.6.2

Treatment

Trypanocides such as Berenil, Samorin, Suramin, and Antrycide, but drug resistance is a problem.

26.13.1.1.6.3

Control

Integrated methods involving tsetse fly control, prophylaxis, good husbandry and use of trypanotolerant breeds, no vaccine.

26.13.1.2

EPIDEMIOLOGY

26.13.1.2.1

Occurrence

The epidemiology of African trypanosomosis is determined mainly by the ecology of the tsetse fly which is found only in tropical Africa. *T. vivax* is also transmitted mechanically by biting flies and occurs also in Central and South America. Affected countries include Bolivia, Brazil, Colombia, French Guiana, Guyana, Peru, Suriname, and Venezuela where it affects mainly cattle and sheep.[1] Whereas *T. congolense* and *T. vivax* are responsible for severe disease in cattle, sheep and goats, *T. brucei brucei* usually causes a subclinical infection in cattle, but a severe disease in sheep, goats, horses and, occasionally, pigs. *T. simiae* causes a very acute and highly fatal disease in exotic pigs. It is not pathogenic to cattle, sheep, or goats.

26.13.1.2.2

Prevalence

Infection rates in cattle in endemic areas vary considerably and could be over 60%. However, as a result of various control methods, the prevalence is decreasing in many African countries, particularly in West Africa, and was as low as 10% in Mali in the 1980s.[2] In a 1989–1991 survey involving approximately 20 000 cattle, 3000 sheep, and 3000 goats in Nigeria, the prevalence was 4.3% in cattle, 1.6% in sheep, and 1.0% in goats, based on parasite detection.[3] Higher prevalence rates are obtained if diagnosis is based on serology, but this does not reflect current infection. *T. vivax* and *T. congolense* are the species most frequently encountered in ruminants, but with serology *T. brucei* is also frequently reported. Mixed infections with two or three species are common. Pigs and horses are less frequently affected than ruminants, perhaps because they are less exposed to tsetse flies than cattle that normally graze over long distances. In Central and South America, *T. vivax* infections appear to be spreading to new areas where they cause periodic outbreaks of serious disease in cattle.

26.13.1.2.3

Morbidity and case fatality

Morbidity rates during outbreaks are variable and may reach 70% in cattle infected with *T. vivax* and up to 100% in pigs infected with *T. simiae*. It is usually much lower in sheep, goats, and horses since these are not often the preferred hosts for tsetse or are less exposed to tsetse challenges. Sheep and goats are more vigorous than cattle in defending themselves against successful feeding by tsetse flies. Case fatality also depends on 1532
parasite species, host, and its level of resistance. *T. simiae* is invariably fatal in exotic 1533
pigs. Some strains of *T. vivax* in East Africa cause similar heavy mortalities in exotic dairy cows, and infected horses are likely to die if left untreated. However, most infections in cattle in endemic areas run a chronic course and are not invariably fatal, but the animal may remain unproductive and unthrifty.

26.13.1.2.4

Methods of transmission

26.13.1.2.4.1

Cyclical

African trypanosomes can be transmitted by 23 species of tsetse (*Glossina*) found only in sub-Saharan Africa between latitudes 14°N and 29°S, excluding areas of high altitude, extreme drought or cold temperatures where tsetse cannot survive. Tsetse species can be grouped according to their preferred habitats as savannah species, riverine species, and forest species. The savannah species (including *G. morsitans, G. austeni, G. pallidipes*, *G. swynnertoni*, and *G. longipalpis*) pose the greatest threat to livestock because they inhabit grasslands where cattle are traditionally reared, they can easily adapt to other ecological niches, they feed primarily on cattle and pigs, and they are efficient vectors of trypanosomes. They are also the main vectors of Rhodesian sleeping sickness associated with *T. brucei rhodesiense* in humans (Table 26.7). The riverine species (*G. palpalis, G. tachinoides*, and *G. fuscipes*) are important as vectors of bovine and porcine trypanosomosis, as well as of Gambian sleeping sickness due to *T. brucei gambiense*. On the other hand, the 13 or so forest species (including *G. fusca, G. brevipalpis*, and *G. longipennis*) are not frequently incriminated vectors of trypanosomes even though their preferred food hosts are ruminants and suids.

The life cycle of trypanosomes in tsetse involves cyclical development for a varying length of time, depending on species and ambient temperatures. *T. vivax* completes its developmental cycle in the proboscis and pharynx and can be transmitted (as

metacyclic trypanosomes) within a week of the initial infective feed. The cycle of *T. congolense* involves the midgut and proboscis and is completed in about 2 weeks. That of *T. brucei* is more complex: it takes 3 or more weeks and involves the midgut and salivary glands. Once infected, flies remain so for life (1–2 months). It follows that for any fly, its vectorial capacity and efficiency are highest for *T. vivax* and least for *T. brucei*.

26.13.1.2.4.2

Non-cyclical

After trypanosomes have been introduced into a herd, transmission is possible even in the absence of *Glossina*. Biting flies such as Tabanidae, Stomoxyinae, and Hippoboscidae are capable of mechanically transmitting trypanosomes in their mouth parts if they feed on more than one host within a short interval. This is how *T. vivax* is spread in areas outside the tsetse belt in Africa, as well as in Central and South America. Mechanical transmission can also occur through the needle during inoculations and in carnivores feeding on infected carcasses. Intrauterine infections occasionally occur.[4]

26.13.1.2.4.3

The carrier state

Reservoirs of infection are found in many wild animals, in trypanotolerant animals, and in chronically infected animals. Tsetse caught in and around game reserves tend to have relatively high infection rates and the relative abundance of wildlife in East Africa as compared to West Africa may explain, at least in part, why the prevalence of the disease appears to be declining more rapidly in the west.

26.13.1.2.5

Risk factors

26.13.1.2.5.1

Host factors

The effect of infection varies with the host in that most wild animals, and some domestic ones, establish a balance with the parasite and remain as clinically normal carriers for long periods. Specifically, some breeds of cattle indigenous to Africa can tolerate light to moderate challenge with tsetse flies by limiting the multiplication of trypanosomes in their blood and by apparently warding off the infection, especially *T. vivax*.[5] The phenomenon is called **trypanotolerance**, it is both genetic and environmental in origin, and the level of tolerance varies. Thus, the indigenous taurine

breeds, such as the N'Dama, Baoule and Muturu, are more tolerant than the West African zebu,[6] and amongst East African zebu cattle, the Orma Boran and Maasai zebu have superior tolerance when compared with Galana Boran and Friesian breeds.[5,7] Crossbreeds of indigenous taurine and zebu animals are also more tolerant than purebred zebu. However, due to the uncertain genetic makeup of animals within these so-called breeds and crossbreeds, the level of trypanotolerance may also vary with individual animals within a given category and it can be overcome by heavy tsetse challenge, malnutrition, or other stress factors. Trypanotolerance also occurs in some indigenous breeds of small ruminants, notably the West African Dwarf sheep and goats and the East African goats, whereas the Toggenburg, British Alpine, Saanen, and Anglo-Nubian breeds of goats are fully susceptible.

26.13.1.2.5.2

Environmental factors

The density of tsetse population in the area, and the level of their contact with the host, will determine the level of infection. This is further influenced by the vectorial capacity of the fly and the availability of its preferred host, which may not be livestock. Trekking of cattle through tsetse-infested vegetation is a risk nomadic farmers face from time to time and the risk is even greater where cattle routes converge, for example, at major bridges or watering holes. Agricultural and industrial developments generally lead to a lowering of tsetse density by destroying its habitat, whereas the establishment of game or forest reserves provides large numbers of preferred hosts or a suitable habitat for tsetse, respectively. Herds located near such reserves are therefore at a higher risk. So also are tourists visiting game parks.

26.13.1.2.5.3

Pathogen factors

In cattle, *T. vivax* generally produces a higher level of parasitemia than other species. And since its life cycle in the tsetse is also shorter, *T. vivax* is more readily transmitted than the others when animals are newly introduced into a tsetse infested area. Higher parasitemias also facilitate mechanical transmission. On the other hand, *T. brucei* is rarely detectable by direct examination of cattle blood, even though infection can be confirmed through other diagnostic methods. Furthermore, some animals carry infection without showing clinical signs, especially if they are trypanotolerant like the Muturu in Nigeria,[8] or if infected with non-pathogenic genetic types, for example, *T. congolense* kilifi type in cattle.[9]

26.13.1.2.6

Immune mechanisms

Animals recovering from infection with one strain/serodeme or species of trypanosome are not immune to infection with another strain/serodeme or species. This is due to the ability of trypanosomes to readily change their surface coat antigens through a process called **antigenic variation**. The glycoprotein surface coat is continuously shed and replaced by mechanisms not fully understood, but probably induced by antibodies. During each peak parasitemia, a mixture of variable antigenic types of parasites is present, but the dominant antigens determine the specific antibody response. These antibodies kill off the dominant population, leaving others with different dominant antigens; these multiply, and the process continues in cycles until the animal dies or the immune mechanisms catch up with the parasite and the animal recovers. This phenomenon is also responsible for the successive waves of parasitemia in infected animals. Following repeated episodes of infection and recovery (with or without treatment) in an endemic area, animals will encounter a variety of antigenic types and therefore become less susceptible to strains/serodemes in that area.

1533 1534

Infected animals are more susceptible to secondary infections by other microorganisms, particularly bacteria. The mechanisms involved are not fully understood, but may vary with the species of animals. In ruminants, the state of immunosuppression is abrogated once the trypanosomes are eliminated by chemotherapy.

26.13.1.2.7

Experimental reproduction

Infection can be easily reproduced by inoculation of infected blood or other body fluid into a susceptible host. Infected flies can also be fed on the host to transmit the disease. Several laboratory animal models are available and lots of studies are done with mice and rats.

26.13.1.2.8

Economic importance

Tsetse flies infest 10 million square kilometers of Africa involving 37 countries. Hence, nagana is today the most important disease of livestock in the continent. The added risk of human infections has greatly affected social, economic, and agricultural development of rural communities. Since nagana is a wasting disease, affected animals are chronically unproductive in terms of milk, meat, manure, and traction, and the mortality rate can be high. The disease in Africa costs livestock producers and consumers an estimated US

$1340 million each year.[10] The anticipated losses due to *T. vivax* in South America exceed $160 million.[1] Furthermore, the disease may impact on various immunization campaigns in endemic areas due to the fact that it can cause immunosuppression.

26.13.1.2.9

Zoonotic implications

The animal pathogens do not infect humans, but animals can serve as reservoirs of *T. brucei rhodesiense* and *T. brucei gambiense*, the causes of human sleeping sickness, which are morphologically indistinguishable from *T. brucei brucei*. Human infections result from tsetse bites, generally in game parks, forest reserves, and along streams or other rural setting. The incidence has fallen greatly since the early part of the 20th century, but outbreaks still occur from time to time, especially when civil unrests force people into tsetse-infested areas. Up to 100 000 cases are reported per year and *T. brucei gambiense* sleeping sickness has re-emerged as a major public health problem in Central Africa, especially in the Democratic Republic of the Congo, Angola, and Southern Sudan, where civil wars have hampered control efforts.[11]

A rash (chancre) develops at the site of tsetse bite and this is soon followed by fever, persistent headache, and swelling of lymph nodes, spleen, and liver. Weakness and signs of cardiac involvement may be noticed early in the Rhodesian form and the disease is rapidly fatal. The Gambian form is more chronic, lasting for 3 or more years during which the patient gradually wastes away or dies from secondary infection. The parasite invades the cerebrospinal fluid leading to progressive non-suppurative meningoencephalitis which causes the patient to fall asleep often, hence the name sleeping sickness.

26.13.1.2.10

Biosecurity concerns

There are none because the vector requires strict environmental conditions to survive. People working with *T. b. gambiense* and *T. b. rhodesiense* should take precautions to avoid accidental inoculation of themselves or their co-workers with infected material in syringes or tsetse flies.

26.13.1.3

PATHOGENESIS

Nagana in most species is a progressive, but not always fatal disease and the main features are anemia, tissue damage, and immunosuppression. Metacyclic trypanosomes are inoculated intradermally as the fly feeds. They multiply at this site provoking a local skin

reaction (chancre), which is most pronounced in a fully susceptible host and may be slight or absent with some strains or species of trypanosomes. Within the chancre, metacyclic parasites change to trypomastigote form, enter the bloodstream directly or through the lymphatics, and initiate characteristic intermittent parasitemias. Their behavior thereafter depends largely on the species of trypanosome transmitted and the host. *T. vivax* usually multiplies rapidly in the blood of cattle, sheep and goats, and is evenly dispersed throughout the cardiovascular system, whereas *T. congolense* tends to be aggregated in small blood vessels and capillaries of the heart, brain, and skeletal muscle, and rarely causes heavy parasitemias in ruminants. Both species exert their effect mainly by causing severe anemia and mild to moderate organ damage. The anemia has a complex pathogenesis involving mainly increased erythrophagocytosis, some hemolysis, and dyshemopoiesis. Very acute infections with *T. vivax* in cattle or *T. simiae* in pigs result in fulminating parasitemias and disseminated intravascular coagulation with hemorrhages. Such syndromes resemble a septicemia, and anemia may not be severe.

T. brucei and, rarely, *T. vivax*, have the added capability of escaping from capillaries into interstitial tissues and serous cavities where they continue to multiply. Such infections result in more severe organ damage in horses, sheep, and goats, in addition to anemia. The cerebrospinal fluid is often invaded by *T. brucei* alone[12,13] or mixed with other species, or as a relapse after an apparently successful treatment.[12,14]

Animals chronically infected with any pathogenic trypanosome may develop concurrent and even fatal bacterial, viral, and other protozoan infections as a result of immunosuppression. Pregnant animals may abort, and transplacental fetal infections occasionally occur. Trypanotolerant animals control parasitemias better and have less severe anemia and organ damage. They usually recover from the disease, but may act as carriers.

26.13.1.4

CLINICAL FINDINGS

There are no pathognomonic signs that would help in pinpointing a diagnosis. The general clinical picture is as follows but there are many variations determined by the level of tsetse challenge, the species and strain of the trypanosome, and the breed and management of the host. Acute episodes last for a few days to a few weeks from which the animal dies or lapses into a subacute to chronic stage, or the illness may be chronic from the beginning. Chronic cases may run a steady course, may be interrupted by periodic incidents of severe illness, or undergo spontaneous recovery.

The basic clinical syndrome appears after an incubation period of 8–20 days. There is fever, which is likely to be intermittent and to last for a long period. Affected animals are dull, anorexic, apathetic, have a watery ocular discharge, and lose condition. Superficial lymph nodes become visibly swollen, mucous membranes are pale, diarrhea occasionally occurs, and some animals have edema of the throat and underline. Estrus cycles become irregular, pregnant animals may abort, and semen quality progressively deteriorates.[15,16] The animal becomes very emaciated and cachectic and dies within 2–4 months or longer. Thin, rough-coated, anemic, lethargic cattle with generalized lymph node enlargement are said to have a 'fly-struck' appearance.[17]

In general, *T. congolense* is more pathogenic to cattle in eastern and southern Africa, whereas *T. vivax* produces a more serious disease in West Africa. However, severe outbreaks of *T. vivax* involving exotic dairy animals in East Africa occur; affected animals show mucosal petechiation, rhinorrhagia, dysentery, and death after an illness of only a few weeks. Mixed infections are common and are usually more severe. Furthermore, intercurrent bacterial, viral, or other parasitic infections may mask or complicate the basic clinical syndrome. Immune response to bacterial, and some viral, vaccines is also depressed but is restored if trypanocidal therapy is given at the time of vaccination.[18]

1534

1535

Clinical findings peculiar to the individual trypanosome are as follows:

- *T. vivax* affects all agricultural species except pigs. Acute and chronic outbreaks occur, anemia is severe, and fever is usually associated with high parasitemia. A chronic form of the disease is more usual in East Africa, but an acute hemorrhagic form can occur with exotic cattle. *T. vivax* is less commonly seen in trypanotolerant cattle breeds
- *T. congolense* affects all species, usually with an acute disease lasting 4–6 weeks, but some chronic cases occur, especially in West Africa. Anemia and emaciation are severe
- *T. brucei* affects all species with a subacute to chronic disease in which subcutaneous edema and keratoconjunctivitis may be marked. Nervous signs are manifested in horses, pigs, and small ruminants by ataxia, circling, head pressing, and paralysis.[19,20] Cattle are usually asymptomatic, with few exceptions[21]

- *T. simiae* affects exotic pigs with a fulminating infection in which the animal dies within hours or a few days of first appearing ill. There is fever, stiff gait, dyspnea, and cutaneous hyperemia, but no significant anemia.

26.13.1.5

CLINICAL PATHOLOGY

The anemia results in a progressive drop in packed cell volume, a non-specific but useful indicator in endemic areas. The classic method of confirming diagnosis is to demonstrate parasites in a wet blood film, and in a thin or thick blood smear stained with Giemsa. This is easiest in the early stages of the disease when parasitemic peaks correspond with fever. As the disease progresses, parasitemias become infrequent and the intervals between peaks grow longer, even though the animal is still sick. To increase the accuracy of parasitological diagnosis, it is now routine to concentrate the parasites in the buffy coat layer of a microhematocrit capillary tube. The buffy layer is then examined directly at low power (Woo's method) or in a wet preparation with a dark ground/phase contrast microscope (Murray's method). Both tests are simple, sensitive, and applicable to field use on individual animals as well as in herds. Blood should be examined fresh but may be refrigerated for up to 24 hours, beyond which most parasites will die and disappear from the sample.[22]

In chronic cases, blood can also be inoculated into experimental animals, usually rodents, but this is cumbersome and is accurate for only *T. brucei*, and possibly *T. congolense*, but not *T. vivax*.

Another alternative is a series of standard serological tests to detect antitrypanosome antibodies in sera or other body fluids. The three tests used most often are the indirect immunofluorescent antibody test (IFAT), the capillary agglutination test (CAT), and the ELISA. These tests have the disadvantage that they indicate past as well as present infections, are difficult to standardize for different laboratories, and are not species-specific. The ELISA technique was modified to detect circulating trypanosome antigens (antigen-ELISA) using monoclonal antibodies that would distinguish between *T. vivax, T. congolense*, and *T. brucei*, and would detect only current or very recent infections.[23] Extensive field trials in Africa and the Caribbean have shown that the test is not sufficiently sensitive or specific and that it needs to be combined with other parasitological methods to provide reliable results.[24]

The polymerase chain reaction (PCR) technique can be used to detect trypanosome DNA in tsetse tissues and in blood.[25] The test is sensitive and species specific and can be combined with ELISA.[26] Under experimental conditions, it can also be used to monitor therapy, especially relapses, since treated animals should become PCR negative 1–2 days after treatment.[27] It is also possible to do retrospective epidemiological survey using serum banks.[28] Dried blood spots on filter papers are also a useful source of DNA for the detection of *T. congolense* and *T. brucei* by PCR.[29] But the test is expensive and can only be done in specialized laboratories.

26.13.1.6

NECROPSY FINDINGS

26.13.1.6.1

Gross pathology

The postmortem lesions are, like the clinical findings, not definitive. The carcass is marked by anemia, emaciation, anasarca, and enlargement of the liver, spleen, and lymph nodes. Body fat stores are depleted or show marked serous atrophy, especially around the heart and in bone marrow. There may be corneal opacity and testicular degeneration. In acute cases, there will be a general congestion of the viscera and extensive hemorrhages in all tissues. Chronic cases show cachexia, often complicated with secondary bacterial or other parasitic diseases.

Microscopic lesions are also not specific, except in very acute infections in which clumps of trypanosomes mixed with fibrin thrombi are found in blood vessels. Lymphoid organs are usually hyperplastic and may show varying degrees of erythrophagocytosis or hemosiderosis. Bone marrow macrophages may engulf red cells as well as other immature and mature cells.[30] The interstitial tissues of various parenchymatous organs may contain a lymphoplasmacytic infiltrate. This tends to be most marked with *T. brucei* in which the parasites often localize extravascularly in the interstitial tissue. A severe non-suppurative meningoencephalitis or myocarditis may result. Degenerative changes may also be present in the liver, testis, and pituitary gland.

26.13.1.6.2

Specimens for pathology

Smears from tissues, usually the cut surface of a lymph node or heart muscle, are examined for trypanosomes. With *T. brucei*, smears of body fluids, including the cerebrospinal fluid may contain many parasites even when they are undetectable in

blood. Trypanosomes die and disintegrate soon after the host dies and will not be seen in smears if postmortem examination is delayed for even a few hours. The following organs should be taken for histopathology: lymph nodes, spleen, liver, heart, kidney, brain, and any other organ showing gross lesions. The immediate cause of death is often a combination of trypanosomosis and a concurrent bacterial or parasitic infection.

26.13.1.6.2.1

DIFFERENTIAL DIAGNOSIS

Diagnosis is based on detecting parasites in blood. Since parasitemias fluctuate, multiple samples from a herd or repeated sampling of a suspected case may be required before a specific diagnosis can be made. Furthermore, infected animals may be suffering from a concurrent disease. Emaciation and anemia can also be associated with:

- Malnutrition
- Helminthosis
- Babesiosis
- Anaplasmosis
- East coast feve

Acute trypanosomosis may be confused with hemorrhagic septicemia and anthrax. Laboratory examination of blood, feces, and other tissues is required to confirm diagnosis.

26.13.1.7

TREATMENT

The number of trypanocidal drugs available for treating and preventing infections in endemic areas is limited, and about 6 million doses are administered yearly in Africa.[31] The drugs have been in the market for over 30 years, their range of therapeutic safety is small, many of them cause severe local reactions especially in horses, and some may be fatal in high doses. Furthermore, as drugs are not always available and they are expensive, underdosing is common. These, plus the fact that some drugs are used both prophylactically and therapeutically, have led to cases of drug resistance.

1535

1536

Ideally, each country or region establishes a group of sanative drugs which are to be used only as a break in a course of one of the more common drugs. The sanative drug should

provide moderate prophylaxis and avoid the development of resistance to the prime drug. These measures have not been well-executed in many countries and this may explain the increasing reports of multiple resistance to curative, sanative, and prophylactic drugs.[32,33] Nevertheless, the prevalence of drug-resistant trypanosomes in the field still remains unclear as there are no suitable methods for the detection of resistant field isolates.[34] For example, drug resistance has been reported to be very low in eastern Zambia[35] but widespread in Burkina Faso[36] and Ethiopia.[37]

Strains are regarded as resistant when they fail to respond to the drug or when they relapse some time after an apparent cure. Relapses are more likely to occur if the commencement of treatment is delayed or the dose rate is inadequate. However, in field situations, there is hardly any regular monitoring of drug efficacy and animals may be reinfected with the same or other species of trypanosomes soon after an otherwise effective cure.

The common drugs in use against trypanosomes are set out below. The specific dose rates vary with animal species, the specific trypanosome, and the specific purpose (curative, prophylactic, or sanative).[31,38]

- Diminazene aceturate (Berenil) is used widely against *T. vivax* and *T. congolense* as a curative and sanative drug at 3.5–7 mg/kg BW. It is well-tolerated by ruminants and it is one of the two recommended drugs for bovine trypanosomosis. It is not well-tolerated by horses
- Homidium bromide (ethidium) and homidium chloride (novidium) are also widely used against *T. congolense* and *T. vivax* as curative and sanative drugs at 1 mg/kg BW
- Isometamidium (Samorin or Trypamidium) is the other preferred drug against *T. vivax* and *T. congolense* in ruminants. It is used as a curative and prophylactic drug at 0.25–1 mg/kg BW. At much higher doses (12.5–35 mg/kg BW) it can be used prophylactically against *T. simiae* in pigs but not without the risk of death from acute cardiovascular collapse[39]
- Pyrithidium bromide (prothridium) is less widely used against *T. congolense* and *T. vivax* as prophylaxis at 2 mg/kg BW
- Quinapyramine sulfate (Antrycide) is no longer used extensively in cattle, but it is the preferred curative drug (at 5 mg/kg BW) against *T. brucei* in horses.

Quinapyramine sulfate and chloride (Antrycide prosalt) is used prophylactically at 7.4 mg/kg BW

- Suramin (naganol) may also be used against *T. brucei* as a curative and prophylactic drug at 10 mg/kg BW in horses and camels
- Antrycide–Suramin complex is the only other drug against *T. simiae* in pigs and it is used prophylactically at 40 mg/kg BW.

26.13.1.8

CONTROL

The control of trypanosomosis in enzootic countries involves control of tsetse fly population, prophylactic treatment, good husbandry of animals at risk, and use of trypanotolerant animals. There is no vaccine against the disease and, in spite of intensive research, none appears likely in the near future because of the ability of trypanosomes to readily change their glycoprotein surface coat through a process called antigenic variation.

Control of tsetse has been successfully attempted in some African countries, but reinvasion is frequent if the land is not properly utilized. The earliest methods involved bush clearing and elimination of game animals on which tsetse feed. These methods were effective in eradicating or controlling tsetse in some parts of the continent, especially in southern Africa, but they resulted in destroying valuable plant and animal resources, and also led to soil erosion. More recent methods involved the use of insecticides, especially DDT and endosulfan, applied strategically in the form of ground and aerial spraying over large expanses of land. As tsetse are sensitive to insecticides and no resistance has developed, considerable successes were achieved in some countries. However, spraying insecticides is costly and harmful to the environment. These harmful effects are considerably reduced if the insecticides, for example, synthetic pyrethroids, are applied directly on the animal in the form of spray or pour-on formulation. The latter offers great promise[40] and also reduces tick infestation in treated animals.

Other effective methods involve targets impregnated with insecticides and traps that attract and catch tsetse. These are simple and cheap and can be constructed and maintained by local communities.[41] Furthermore, they do not pollute the environment and are suitable for both small- and large-scale farming. They have been used to reduce tsetse fly population by over 97% within 7 months in a community in the Congo[42] and to greatly reduce the incidence of trypanosomosis in another community in south-western Kenya over a 12-year period.[43] Another method is the sterile male technique. Since the female tsetse only mates

once in a lifetime, this technique is theoretically able to eradicate a targeted tsetse species in areas where other methods have been used to reduce its density. But it is expensive. Finally, it should be stated that development of the land for agriculture, industries, highways, etc. will effectively destroy the habitat for tsetse flies. This has occurred significantly in Nigeria where there were rapid economic activities and expanding human population in the 1970s and 1980s.[44]

Attempts at trypanosomosis control have also been directed to prophylactic dosing with chemicals such as suramin, prothridium, and isometamidium (Samorin). Prophylaxis is used along with other methods in areas where there is a heavy tsetse challenge. The prophylactic effect is supplemented by the development of antibodies, and the total period of protection may be as long as 5 months. However, it is customary to give four or five treatments per year. The productivity response to this pattern of treatment is good if general husbandry is also adequate. The downside of this approach is that it has reportedly led to drug resistance in many countries.

Trypanotolerant animals are being used to establish ranches in areas where tsetse challenge is not too heavy, but they have not been readily accepted in some countries, supposedly because they are smaller in size and they produce less milk than other indigenous breeds and crosses with exotic breeds.

For effective control of trypanosomosis in Africa and in Central and South America, an integrated approach will mostly likely produce the desired results in each region. In the absence of a vaccine, control methods must combine reduced exposure to the vectors (large scale tsetse trapping and pour-on applications) with strategic treatment of exposed animals (chemotherapy and chemoprophylaxis) along with use of trypanotolerant animals when feasible.

1537

26.13.2 SURRA (MAL DE CADERAS, MURRINA)

26.13.2.1 Synopsis

26.13.2.1.1 Etiology

Trypanosoma evansi (synonym *T. equinum*), morphologically similar to *T. brucei*. Parasites are transmitted mechanically by biting flies, mainly tabanids, and in Latin America, by vampire bats.

26.13.2.1.2 Epidemiology

Endemic disease of mainly horses and camels in the tropics and subtropics, seasonality is related to fly population.

26.13.2.1.3 Pathogenesis

Fly inoculation → parasite multiplication in blood and body fluids → clinical signs.

26.13.2.1.4 Clinical signs

Fever, progressive emaciation, anemia, subcutaneous edema, nervous signs, death. May be acute, subacute, or chronic.

26.13.2.1.5 Clinical pathology

Progressive anemia, parasite detection in blood by various methods, serology.

26.13.2.1.6 Lesions

Not definitive but include palor, emaciation and jaundice.

26.13.2.1.6.1 Differential diagnosis list

- Nagana
- Malnutrition

- Helminthosis
- Babesiosis
- Anaplasmosis
- Hemorrhagic septicemia.

26.13.2.1.6.2 #### Treatment

Trypanocides as in nagana, but less effective.

26.13.2.1.6.3 #### Control

Chemotherapy and prophylaxis, no vaccine.

26.13.2.2 ## ETIOLOGY

Trypanosoma evansi, the first pathogenic trypanosome to be identified in 1880 in India, belongs to the *brucei* group (subgenus *Trypanozoon*) but is not capable of cyclical development in tsetse *Glossina* spp. In blood smears, *T. evansi* is morphologically indistinguishable from *T. brucei*, but at the molecular level, the structure of the kinetoplast DNA of *T. evansi* is different.[1] *T. equinum* in South America is now accepted as a dyskinetoplastic variant of *T. evansi* rather than a separate species.

26.13.2.3 ## EPIDEMIOLOGY

26.13.2.3.1 ### Occurrence

Surra has a wide distribution in areas of Africa north of the tsetse belt and in the Middle East, Asia, and Central and South America. The disease in South America is called ‘mal de caderas’ or ‘murrina’. In some countries, the incidence of surra increases significantly during the rainy season when there are large biting fly populations, the so-called ‘surra season’. The disease affects mainly camels and horses, but buffaloes and cattle are also affected. In South America, surra has not been reported in New World camelids, even though they are susceptible.[2]

26.13.2.3.2

Morbidity and case fatality

Infection rates of 20% are not uncommon in camels living in the northeastern parts of Africa, and they can be as high as 70%.[3] The case fatality in horses and camels is nearly 100% if untreated, but is much lower in cattle and buffalo where the disease tends to run a chronic course.

26.13.2.3.3

Method of transmission

Several hematophagous flies can transmit *T. evansi* mechanically, but the most important is the horse fly (*Tabanus* spp.), followed by the stable fly (*Stomoxys* spp.). Transmission is enhanced when horses or camels congregate or are closely herded and when they have high numbers of parasites in their blood. In South America, the vampire bat also transmits the disease in its saliva. The process can be mechanical as for flies but also biological in that parasitemia occurs in the bats which may die from the infection or recover and serve as carriers. Therefore, vampire bats are simultaneously hosts, reservoirs, and vectors of *T. evansi*.[4] Carnivores can also be infected perorally when they feed on an infected carcass.

Indigenous cattle, buffalo, and several species of wildlife may act as reservoirs of infection for horses and camels. Immune mechanisms are related to antigenic variation of the parasite and the production of antibodies by the host, as in *T. brucei*. The disease can be reproduced experimentally by blood inoculation. Humans are not susceptible.

26.13.2.3.4

Economic importance

Surra is one of the most important diseases of camels. Camel raising in Africa and buffalo production in Asia are severely affected by the disease. As in nagana, losses are due to reduced productivity, mortality, and cost of treatment. In Indonesia, surra is ranked as the third most important livestock disease, with losses in 1984 estimated at more than US$20 million.[5]

26.13.2.3.5

Biosecurity concerns

There are none.

26.13.2.4

PATHOGENESIS

Trypanosomes are inoculated into the host from the contaminated mouthparts of biting insects or the saliva of vampire bats. Parasite multiplication in the blood and body fluids causes inflammatory changes and anemia just like *T. brucei*.[6] The parasite frequently localizes extravascularly in tissues including the central nervous system where it is less exposed to chemotherapeutic agents.

26.13.2.5

CLINICAL FINDINGS

1537
1538

The main clinical findings are intermittent fever, progressive anemia, edema of dependent parts of the body, dullness, listlessness, loss of body condition despite a good appetite, nasal and ocular discharge, and terminal nervous signs, including paraplegia, paralysis, delirium, and convulsion.[1–4] Surra is invariably fatal in camels and horses, death occurring within a few days or a few months, but camels may exhibit chronic signs for years. These signs include a reduction in milk yield and capacity for work, and a high abortion rate in pregnant females.[7] Cattle and buffalo in endemic areas usually have mild infections which may be exacerbated by stress from adverse climatic conditions, work, or intercurrent disease. Signs may include irregular estrus, abortion, and stillbirth in cows, and poor semen quality in bulls. Outbreaks of a more severe disease in indigenous zebu cattle have been reported in Thailand, characterized by nervous signs and high mortality rate; the signs included circling, excitation, jumping, aggressive behavior, lateral recumbency, convulsion, and finally death.[8]

26.13.2.6

CLINICAL PATHOLOGY

As with *T. brucei*, parasite detection including the buffy coat method is easier in the acute phase. In the chronic phase, repeated sampling for some days may be required. In addition, suspected blood samples may be inoculated into rats or mice both of which are highly susceptible. A number of non-specific serological tests can also be used but are more reliable in areas where other forms of trypanosomes do not exist. These include mercuric chloride, formol gel, or stilbamidine test for increased serum protein levels. Specific antibody detection tests are also available, but await large-scale evaluation and standardization.[9] They include direct card agglutination test (CAAT) for antibodies, the latex agglutination test (Suratex) for circulating antigens, the indirect fluorescent antibody test (IFAT), and the enzyme-linked immunosorbent assay (ELISA). In a study in Kenya,

CAAT and Suratex were reported to be more sensitive than parasitological methods in revealing the true extent of surra in camel herds,[10] contrary to an earlier study from Chad.[11] Techniques involving the polymerase chain reaction (PCR) have been described; they are more sensitive and specific, but too expensive for routine use.[4,12]

26.13.2.7

NECROPSY FINDINGS

The carcass is emaciated and pale and may be icteric but, as in *T. brucei* infections, there are no pathognomonic gross and microscopic lesions. However, a lymphoplasmacytic infiltrate of various organs, including the brain and spinal cord, is characteristic. Parasites are detectable in body fluids if the carcass is fresh. Tissues for laboratory examination should include blood, brain, lymph nodes, spleen, and liver.

26.13.2.7.1

DIFFERENTIAL DIAGNOSIS

Laboratory services are required to confirm a diagnosis, and even then surra cannot be easily distinguished from *T. brucei* infection where both coexist. Clinical signs and gross and microscopic lesions of both diseases in horses and camels are identical.

26.13.2.8

TREATMENT

Drugs used for treating nagana could be used for surra, but the outcome is less favorable owing to their low trypanocidal activity against *T. evansi* and their specific toxicity for camels and horses. Furthermore, the drugs are not able to cross the blood–brain barrier to reach parasites in the cerebrospinal fluid and nervous tissue. As a result, drug resistance readily occurs, especially if the accurate dose is not given.

Quinapyramine sulfate (quintrycide) is used curatively for camels, and diminazene aceturate (Berenil) for horses and camels. On the other hand, quinapyramine prosalt (trypacide), suramin (naganol) and isometamedium chloride (samorin or trypamidium) are used both curatively and prophylactically. The new drug is a water-soluble arsenical, RM110 or Cymerlasan (melarsomine), given SC at 0.3–0.6 mg/kg BW. It is as effective as berenil in infected camels.[7,13]

26.13.2.9

CONTROL

Unlike in nagana, control measures are aimed primarily at the host rather than the vector, which is abundant. The measures include detection and treatment of infected animals,

prophylactic treatment of susceptible animals, and their protection from biting flies and bats, where possible. As in nagana, there is no vaccine.

26.13.3 # DOURINE (MALADIE DU COIT)

26.13.3.1 ## Synopsis

26.13.3.1.1 ### Etiology

Trypanosoma equiperdum.

26.13.3.1.2 ### Clinical signs

Primary genital signs, secondary cutaneous signs and tertiary nervous signs.

26.13.3.1.3 ### Epidemiology

Venereal disease of horses, mules, and donkeys, endemic in southern and northern Africa, Asia, and possibly South and Central America.

26.13.3.1.4 ### Pathogenesis

Transmission during coitus → infection of genital mucosa → parasitemia → localization in skin and nervous system → edema and nervous signs.

26.13.3.1.5 ### Clinical pathology

Serology; rarely, parasite detection in edema fluid and blood.

26.13.3.1.6 ### Lesions

Edematous swelling and later, depigmentation of external genitalia, emaciation, anemia and subcutaneous edema.

26.13.3.1.6.1 #### Differential diagnosis list

- Nagana
- Surra
- Coital exanthema
- Equine infectious anemia.

26.13.3.1.6.2

Treatment

Chronic cases unresponsive to trypanocides and they often become carriers.

26.13.3.1.6.3

Control

Elimination of reactors, control of breeding and movement of animals in affected regions or countries.

26.13.3.2

ETIOLOGY

Trypanosoma equiperdum belongs to the *brucei* group, subgenus *Trypanozoon*, but occurs only as long, slender, and monomorphic forms and is morphologically indistinguishable from *T. evansi*. It is the only pathogenic trypanosome that does not require an arthropod vector for its transmission and it resides more in extravascular tissue fluid than in blood.

26.13.3.3

EPIDEMIOLOGY

26.13.3.3.1

Occurrence

Dourine is endemic in northern and southern Africa and Asia, and possibly South and Central America. However, it has not been reported in Latin America for over 15 years, possibly due to very strict international regulations which tend to discourage official notification of the disease.[1] Dourine has been eradicated from North America and there are no recent reports of outbreaks in Europe, probably because of strict control measures. It is rare in sub-Saharan Africa, other than Ethiopia and Namibia. All Equidae are susceptible and natural infection is known to occur only in horses, mules and donkeys.

1538

1539

26.13.3.3.2

Measures of disease occurrence

The prevalence of dourine has declined generally since the horse is no longer that important militarily, economically, and agriculturally, and because of strict control measures in many countries. Recent reports, based on clinical signs and serology, indicate a prevalence in some herds to be as high as 7% in Mongolia,[2] 28% in Ethiopia,[3] and 29 % in Namibia.[4] In South and Central America and in Europe, the disease occurs sporadically. Case mortality rate varies; in Europe it could be as high as 50–75%, but is

much less elsewhere although many animals may have to be destroyed as a means of control.

26.13.3.3.3

Methods of transmission

Natural transmission occurs only by coitus, but infection can also be acquired through intact oral, nasal and conjunctival mucosae in foals at birth. The source of infection may be an infected stallion or mare actively discharging trypanosomes from the urethra or vagina, or an uninfected male acting as a physical carrier after serving an infected mare. The trypanosomes inhabit the urethra and vagina, but disappear periodically so that only a proportion of potentially infective matings result in infection. Invasion occurs through intact mucosa, no abrasion being necessary.

26.13.3.3.4

Risk factors

T. equiperdum is incapable of surviving outside the host and, like other trypanosomes, it dies quickly in cadavers. Some animals may be clinically normal but act as carriers of the infection for many years. Since the disease does not require an arthropod vector for its transmission, and in view of the extensive movement of horses across continents that now takes place, the risk of infection, though small, is present in every country, as with any other venereal disease. Thoroughbred horses are more susceptible than indigenous horses, and donkeys tend to show more chronic signs.

26.13.3.3.5

Immune mechanisms

Infected animals produce antibodies to successive antigenic variants, as in *T. brucei*. Recovered animals often become carriers. Blood from infected horses is rarely infective to other horses, and the disease is not easily transmitted to ruminants under experimental conditions. Humans are not affected.

26.13.3.3.6

Biosecurity concerns

There are none.

26.13.3.4

PATHOGENESIS

T. equiperdum shows a remarkable tropism for the mucosa of genital organs, the subcutaneous tissues, and the peripheral and central nervous systems. Trypanosomes

deposited during coitus penetrate the intact genital mucosa, multiply locally in the extracellular tissue space, and produce an edematous swelling which may later undergo fibrosis. Subsequent systemic invasion occurs and localization in other tissues causes vascular injury and edema, manifested clinically by subcutaneous edema. Invasion of the peripheral nervous system and the spinal cord leads to incoordination and paralysis.

26.13.3.5

CLINICAL FINDINGS

The severity of the clinical syndrome varies depending on the strain of the trypanosome and the general health of the horse population. The disease in Africa and Asia is much more chronic than in South America or Europe and may persist for many years, often without clinical signs, although these may develop when the animals' resistance is lowered by other disease or malnutrition.

The incubation period varies between 1 and 4 weeks, but could extend to more than 3 months in some animals. Initial signs may not be recognized until the breeding season. The ensuing disease will manifest genital signs in the primary stage, cutaneous signs in the secondary stage, and nervous signs in the tertiary stage.[5]

In the stallion, the **initial signs** are swelling and edema of the penis, scrotum, prepuce, and surrounding skin, extending as far forward as the chest. Paraphimosis may occur and inguinal lymph nodes are swollen. There is a moderate mucopurulent urethral discharge. In mares, the edema commences in the vulva and is accompanied by a profuse fluid discharge, hyperemia, and sometimes ulceration of the vaginal mucosa. The edema spreads to the perineum, udder, and abdominal floor. In Europe, the disease is more severe, genital tract involvement often being accompanied by sexual excitement and more severe swelling.

In the **secondary stage**, cutaneous urticaria-like plaques, 2–5 cm in diameter, develop on the body and neck and disappear within a few hours up to a few days. These so-called ‘silver dollar spots’ are pathognomonic for dourine but are not always present, and are uncommon in endemic areas. Succeeding crops of plaques may result in persistence of the cutaneous involvement for several weeks.

The **tertiary stage** is characterized by progressive anemia, emaciation, weakness, and nervous signs appearing at a variable time after genital involvement. Stiffness and weakness of the limbs are evident and incoordination develops, progressing terminally to ataxia and paralysis. Marked atrophy of the hindquarters is common and in all animals

there is loss of condition, in some to the point where extreme emaciation necessitates destruction. Lack of coordination of the hind legs, swelling of the external genitalia, and emaciation were the most common clinical signs in horses suspected to have dourine in Ethiopia.[3]

26.13.3.6

CLINICAL PATHOLOGY

Trypanosome detection is difficult, but should be attempted in edema fluid, subcutaneous plaques, and vaginal or urethral washings or blood in early stages. Inoculation of blood into laboratory rodents is not as helpful as with other members of the *brucei* group. An efficient complement fixation test (CFT) is available and was the basis for a successful eradication program in Canada, but there are discrepancies in some of the CFT results.[6] Other serological tests that can be used include the indirect fluorescent antibody test (IFAT), the capillary agglutination test for trypanosomes (CATT), and the enzyme linked immunosorbent assay (ELISA), but the CFT remains the most reliable.[5,7] Serological tests do not distinguish between members of the *brucei* group and hence they are of limited value in areas where *T. brucei* or *T. evansi* is endemic, even when monoclonal antibodies are used. The polymerase chain reaction (PCR) has been used to detect trypanosome DNA and is an indication of an active infection, unlike the CFT which detects past and current infections. But the PCR test cannot yet distinguish *T. equiperdum* from *T. evansi*. Furthermore, it has not been possible to isolate new strains of *T. equiperdum* from clinical cases that have appeared in various parts of the world since 1982.[6,8] Therefore, new internationally recognized tests for the diagnosis of dourine are needed urgently.

26.13.3.7

NECROPSY FINDINGS

Emaciation, anemia, and subcutaneous edema are always present, and edema of the external genitalia may be evident or the external genitalia may have healed, leaving the characteristic depigmented scars of permanent leukodermic patches.[5] Lymph nodes are enlarged and there is softening of the spinal cord in the lumbosacral region.

Histological lesions consist of lymphoplasmacytic infiltration in the spinal nerves, ganglia, and meninges of the lumbar and sacral regions, and in affected skin and mucosa. Trypanosomes can be found in sections of the skin and genital mucosa during the primary and secondary phases of the infection. Affected lymph nodes show non-specific lymphoid hyperplasia.

1539 1540

26.13.3.7.1

DIFFERENTIAL DIAGNOSIS

The full clinical syndrome is diagnostic, when present, since no other disease has the clinical and epizootiological characteristics of dourine. However, when the full clinical picture is not developed, other diseases like nagana, surra, coital exanthema, equine infectious anemia, and purulent endometritis should be considered. Recent reports of the disease have been based on clinical signs, serology and detection of trypanosome DNA, but not on parasitological detection.

26.13.3.8

TREATMENT

Many trypanocidal drugs have been used in the treatment of dourine, but results are variable, chronic cases in particular being unresponsive to treatment. Berenil (diminazene) at 7 mg/kg BW as a 5% solution injected IM, with a second injection of half the dose 24 hours later, or suramin (10 mg/kg IV for two to three treatments at weekly intervals), or quinapyramine sulfate (3–5 mg/kg in divided doses injected SC) have been tried. The main drawback is that treated animals may remain inapparent carriers.

26.13.3.9

CONTROL

In dourine-free countries, an embargo should be placed on the importation of horses from countries where the disease is endemic, unless the animals have been properly tested and found negative. Eradication on an area or herd basis is by the application of the CFT, along with strict control of breeding and movement of horses. Positive reactors are disposed of, and two negative tests not less than a month apart can be accepted as evidence that the disease is no longer present. Castration or neutering of infected animals is not adequate because mating can still occur.

27 Chapter 27 Diseases associated with helminth parasites

27.1 Nematode diseases of the alimentary tract

27.1.1 Parasitic gastroenteritis in ruminants

27.1.1.1 Synopsis

27.1.1.1.1 Etiology

The nematode genera *Trichostrongylus, Ostertagia* (including *Teladorsagia*), *Cooperia*, and *Nematodirus*.

27.1.1.1.2 Epidemiology

Transmission is by ingestion of infective larvae. Disease risk is determined by factors influencing the susceptibility of the host, the numbers of infective larvae accumulating on pasture and the numbers of larvae undergoing hypobiosis within the host. Calves and lambs are most vulnerable, as are goats of all ages. Type I disease follows recent infestation; Type II disease is delayed until hypobiotic larvae resume development.

27.1.1.1.3 Signs

Diarrhea and weight loss, production losses.

27.1.1.1.4 Clinical pathology

High fecal egg count (in young animals) (unless disease caused by immature worms), elevated plasma pepsinogen and gastrin concentrations (in abomasal infections only).

27.1.1.1.5 Lesions

Raised nodules on gastric mucosa and/or inflammation and villous atrophy in anterior small intestine.

27.1.1.1.6 Diagnostic confirmation

Worm counts at necropsy, otherwise largely reliant on clinical signs and history. Fecal egg counts and plasma pepsinogen concentrations confirmatory in some instances.

27.1.1.1.7

Treatment

Avermectins/milbemycins; benzimidazoles/probenzimidazoles; levamisole and morantel. Not all compounds are suitable for controlling hypobiotic larvae.

27.1.1.1.8

Control

Methods differ widely according to climatic region and management. The major aim is to maintain safe grazing by reducing pasture contamination. Integrated management schemes which reduce dependence on drug usage are preferred as anthelmintic resistance is a serious or emerging problem in many areas, particularly in sheep and goats.

27.1.1.2

ETIOLOGY

The nematode genera *Trichostrongylus*, *Ostertagia*, *Cooperia*, and *Nematodirus* (known locally as scour worms or hair worms) often occur together in the alimentary tract of ruminants. Their combined effects on the host, together with those of other alimentary nematodes such as *Oesophagostomum* and the hookworms, are commonly known as parasitic gastroenteritis (PGE). The main species are listed in Table 27.1 together with their hosts and anatomical preferences. The listed worms are from the same nematode family and are collectively known as the trichostrongylids. *Haemonchus* also belongs to this group but is considered separately as the disease processes it provokes are more complex. Taxonomists now believe that the *Ostertagia* species of sheep should be assigned to a different genus, *Teladorsagia* and *Nematodirus* to a different family, but the clinical convenience of the older nomenclature has been retained for the purposes of this chapter. Related species from other hosts, for example *Ostertagia leptospicularis* from deer, sometimes cause disease outbreaks in cattle.[1]

27.1.1.3

LIFECYCLE

The trichostrongylids all have direct lifecycles (i.e. there is no intermediate host). Eggs passed in the feces hatch under suitable environmental conditions, producing two non-parasitic larval stages and then the infective third-stage larva. This is ensheathed, i.e. it retains the shed cuticle from the previous molt for protection. The eggs of *Nematodirus* spp. are different from the others. They are larger and do not hatch initially. Instead, an infective ensheathed larva develops within the egg thereby gaining even greater resistance

to harsh environmental conditions. When infective trichostrongylid larvae are ingested by the host, they exsheath and depending on species, enter either the gastric glands of the abomasum or the crypts of the small intestine. Here they molt, return to the lumen and after a fourth molt mature to become adult. The time from ingestion of larvae to appearance of egg-laying females (the prepatent period) normally takes about 3 weeks, except for *Nematodirus*, which takes a week or so more. This period may become extended as third- or early fourth-stage larvae, depending on species, can become arrested in development (hypobiotic) thereby delaying emergence from the mucosa for weeks or months.

1541

1542

Table 27.1 Anatomical distribution of trichostrongylid worms in ruminants

Parasite	Cattle		Sheep, goats	
	Abomasum	Small intestine	Abomasum	Small intestine
Trichostrongylus spp.				
T. axei†	*		*	
T. colubriformis, T. longispicularis		*		*
T. falculatus, T. vitrinus, T. capricola, T. rugatus T. probolurus				*
Ostertagia spp.				
O. ostertagi	*			
O. circumcincta,‡ *O.trifurcata*‡			*	
Cooperia spp.				
C. punctata, C.oncophora		*		*
C. pectinata		*		
C. curticei				*
Nematodirus spp.				
N. spathiger, N. battus, N. filicollis, N. abnormalis, N. helvetianus		*		*

† *Trichostrongylus axei* also occurs in the stomach of horses.

‡ The genus name *Teladorsagia* is often used in place of *Ostertagia* for these species.

Hypobiosis is probably an adaptation phenomenon similar to diapause in insects and happens during periods of adverse pasture conditions. For example, strains of *O. ostertagi* from northern Europe, the northern United States, and New Zealand undergo hypobiosis in autumn with worms resuming development in spring, while strains in the southern United States and Australia hypobiose in spring to emerge after the dry season in autumn.[2] Thus, hypobiosis ensures that a new generation of adults is ready to lay eggs when the external environment again becomes favorable. The environmental stimuli that condition infective larvae to become hypobiotic in the host vary with species and locality, and in most cases are unknown. For *O. ostertagi* in Europe, exposure of infective larvae to low temperatures in the autumn is the trigger. The proportion of ingested larvae becoming arrested varies greatly with locality and, in some places, also from year to year.

27.1.1.4

EPIDEMIOLOGY

Natural trichostrongylid infestations mostly comprise a mixture of species. The relative importance of each varies with locality and season. In sheep and cattle, *Ostertagia* tends to be of greatest clinical significance in winter rainfall areas while *Haemonchus* is predominant in summer rainfall zones. Other genera may dominate in some areas or under some management practices. Sheep and goats share many trichostrongylid species but cross-infection between sheep and cattle occurs only to a limited extent. Patterns of disease are determined by factors influencing the susceptibility of the host, the numbers of infective larvae accumulating on the pasture and the numbers of larvae undergoing hypobiosis in the host.

Resistance to trichostrongylid infections is complex and involves genetically determined physiological and acquired immunological components. Age resistance is seen particularly in the case of *Nematodirus*, where 3 to 4-month-old lambs are better able to withstand larval challenge than younger animals. Differences in susceptibility occur between breeds and between individuals within a group.[3] Acquired immunity in sheep and cattle develops quickly after exposure to *Nematodirus* but takes much longer with other gastrointestinal trichostrongylids. Consequently, disease associated with *Nematodirus* is only likely to occur at first exposure, but animals remain susceptible to the other trichostrongylids for most or all of the first grazing season. In cattle, exposure to *Cooperia* leads to immunity earlier in the season than is the case with *Ostertagia*.[4] Lambs can develop high resistance

to *Trichostrongylus* by about 6 months of age when larval intake is high, but this period is extended when challenge is low.[5] Immunity may be expressed as:

- A reduction in parasite numbers
- Stunted surviving worms
- Lowered egg output by females
- A smaller establishment of incoming larvae.

The term 'resilience' is used to describe the ability of an animal to withstand the damaging effects of parasitic infestation (as distinct from limiting worm numbers). Resistance and resilience can be affected adversely by stress and nutritional deficiencies. Moderate infestations can be tolerated by animals on a good plane of nutrition when similarly infected but poorly nourished animals would succumb. In weaner lambs, the reduction of food intake at weaning increases susceptibility, while the poor quality of winter feed has the same effect in older stock. Massive infestations can overwhelm even well-fed animals.

A relaxation in immunity to trichostrongylid infection occurs in sheep but not cattle before or at the time of parturition and reaches a peak 6–8 weeks after lambing. This happens because priority is given for allocation of scarce metabolizable protein to milk production over immune functions.[6] As a result, ewes pass large numbers of worm eggs onto the pasture over a period of several weeks. This is known as the periparturient egg rise (PPER) and is an important source of pasture contamination.

***Nematodirus* spp. behave differently** from other trichostrongylids. This genus does not contribute to the PPER in ewes and so lambs are the sole source of contamination on sheep pastures. *Nematodirus* eggs containing the infective third-stage larvae hatch only after exposure to specific stimuli, particularly warmth after a period of low temperatures. Thus, most hatch in the spring of the year following that in which they were deposited (although a proportion may hatch in the autumn of the first year).[7] Unlike the other trichostrongylids, therefore, *Nematodirus* is transmitted from one lamb crop to the next. *N. battus* is more pathogenic than the other species because its hatching requirements are more precise. This results in many eggs hatching simultaneously to produce a sudden overwhelming wave of pasture contamination.

The eggs and free-living larvae of *Trichostrongylus*, *Ostertagia*, *Cooperia*, and *Nematodirus* can survive and develop at much lower temperatures than those of *Haemonchus*. The eggs and larvae of *Ostertagia* and *Nematodirus* are particularly resistant to cold temperatures. The eggs of the latter worm contain trehelose, which acts as an antifreeze.[8] All these trichostrongylids can survive a moderate winter but the spectrum of endemic species declines as regional winter conditions become more severe.[9] Snow cover however protects infective larvae from extreme cold. Upper temperature limits for survival are also lower than for *Haemonchus* and this is why the clinical importance of *Ostertagia* spp. diminishes in warmer climates. Moisture is necessary for infective larvae to ascend the herbage and so transmission by all species is low in the absence of dew, rain or irrigation. Desiccation will kill larvae on the pasture but those still within fecal deposits can survive to emerge when rainfall resumes. Severe outbreaks of disease may occur after the first rains following a prolonged drought. Summer storms during a dry period reduce risk as released larvae quickly die when the pasture dries out.[10] In temperate climates, larvae leaving accumulated dung pats in the autumn after a dry summer may be conditioned for hypobiosis, thereby increasing risk of Type II disease (see ‘Outbreaks of disease' below).

Potential sources of contamination on sheep pastures at the start of the grazing season are larvae that have overwintered on the herbage and, most importantly, larvae from eggs more recently shed by ewes during the PPER. On cattle pastures, overwintered larvae are of greatest significance as yearling and adult cattle generally deposit insignificant numbers of trichostrongylid eggs. In both cases, overwintered larvae do not survive long in the warmer spring weather as the food stores on which they depend are soon exhausted. In the meantime, however, some will be ingested by susceptible lambs or calves. Disease does not occur at this stage unless massive numbers of larvae have survived the winter. Most often, these first infections are small and asymptomatic. They are nevertheless of great epidemiological significance as the eggs produced are responsible for the infective larvae that appear on the pasture later in the season.

The rate of larval development is temperature dependent, occurring faster in warmer weather. The lifespan of infective larvae is, however, shorter at higher temperatures as food stores are used more quickly. The number of larvae accumulating on pasture is therefore a balance between these two opposing factors and tends to follow a stereotyped pattern in each locality. Computer models are being developed to investigate these trends in different climatic zones and under different husbandry systems.[11] The general pattern of

pasture infectivity may however be temporarily disrupted by short-term weather fluctuations. For example, with *O. ostertagi* in grazing calves in temperate climates, the new wave of infective larvae (the ‘autoinfection peak') will not appear before mid-summer, but this event may be delayed or interrupted by periods of dry weather. As larvae of each trichostrongylid species have different optimum developmental conditions, peak numbers will occur at different times. In England, for example, the ‘succession of species' in sheep is *N. battus* followed by *O. circumcincta* then *H. contortus* and finally *Trichostrongylus* spp.[12]

Outbreaks of disease due to trichostrongylid infection can occur in different ways. Clinical signs are normally initiated when developing worms emerge from the mucosa of the alimentary tract. With normally developing mucosal larvae, this will happen when the daily intake of infective larvae has risen to a level sufficient to overwhelm any immunity that may have developed. This is sometimes termed ‘Type I' disease. The onset of clinical signs will be considerably delayed however when damage is produced by previously hypobiotic larvae resuming their development. This often occurs during the winter housing period and is known as ‘Type II' disease. Additionally, hypersensitivity responses to incoming larvae can occur under some circumstances when immune animals graze heavily contaminated pasture. This has been proposed as an explanation for the so-called ‘non-parasitic scouring syndrome' in southern Australia, which occurs in pregnant and lactating ewes grazing contaminated pasture.[13]

Trichostrongylosis in sheep is favored by cool, wet weather and is a disease of the winter months in those areas where rainfall occurs chiefly at this time of the year. Although the eggs and larvae of *Trichostrongylus* spp. tolerate cold, they are not resistant to freezing temperatures. Consequently, in very cold climates disease may be more common in the late summer and autumn. In arid areas the disease is of little significance except in unusually wet years. *T. axei* can infect a range of species but is primarily a parasite of cattle and is usually only seen in other hosts when grazing cattle pastures.

The epidemiology of bovine ostertagiosis is complex. Type I disease is mostly seen in first-season grazing animals particularly dairy calves heavily stocked on permanent calf paddocks. Large numbers of adult worms are present and egg counts are high. In areas with warm climates, Type I ostertagiosis may be seen in almost any season but is particularly important in winter and spring. In areas with harsher winters, as in northern Europe, larvae overwinter in sufficient numbers to infect autumn-born calves after spring turnout. The resulting small worm burdens produce eggs that give rise to a new generation

of infective larvae. These ‘autoinfection larvae' are responsible for the disease outbreaks that occur from mid-July to the end of the grazing season. Type I ostertagiosis also occurs in beef cattle if placed on heavily infected pastures immediately after weaning. It is less often seen in calf suckler or extensive management systems because of the relatively low number of susceptible animals per unit area of grazing land.

When hypobiosis occurs, many fourth-stage larvae accumulate in the gastric glands. Few if any clinical signs will be apparent and egg counts will be zero or low. This condition is called pre-Type II ostertagiosis and occurs at a definite time each year depending on the region – autumn in northern Europe and spring in Australia. Type II disease occurs when waves of hypobiotic larvae emerge from the parasitized glands some 4–5 months later. This is typically when cattle are 12–24 months of age, although Type II disease is sometimes seen in older animals. Few adult worms will be present and egg counts will be correspondingly low.

Goats do not build up an effective immune response against trichostrongylid worms and so remain susceptible to disease throughout their lives. The risk is enhanced if they are forced to graze rather than browse. Problems are frequently encountered on hobby farms where goats are overstocked on small paddocks.

27.1.1.5

PATHOGENESIS

Each trichostrongylid species differs in its habit and in the damage it causes and so details of the corresponding disease processes will vary correspondingly. The major mechanisms leading to diarrhea, weight loss and production deficits can however be described in general terms.

In abomasal infection with *Ostertagia* spp., developing larvae distend the gastric glands and produce small white nodules on the mucosal surface, but these are of little clinical significance. More important changes take place 18–21 d after infection when worms start to emerge from the glands.[14] This triggers a hyperplastic reaction in neighboring glands causing larger nodular lesions which, if numerous, may coalesce. Many of the cells lining affected glands are non-functional. The resulting reduction in acid-secreting parietal cells leads to increased gastric pH, which may rise to 6–7. This produces several domino effects. First, incoming bacteria and ruminal protozoa are not killed. Second, pepsinogen is not converted to pepsin as this only happens in an acid environment, thus, no pepsin is available for protein digestion. Accumulating amounts of the precursor molecule are reflected in elevated blood pepsinogen concentrations. Third, blood gastrin rises as the

1543 1544

body attempts to stimulate more acid secretion. The hyperplastic mucosal reaction also results in increased permeability of the epithelial sheet. This leads to protein loss into the lumen of the abomasum. In mild uncomplicated cases, this protein leak and the disrupted protein digestion are both compensated by digestive/absorptive intestinal mechanisms. In severe cases, hypoalbuminemia, tissue edema and weight loss are apparent. Between these extremes, these processes lead to reduced muscle protein synthesis and consequent productivity losses.[15]

Intestinal trichostrongylid infections are associated with inflammatory changes, a thickening of the mucosa and a stunting or flattening of the villi. Epithelial enzyme activity is reduced. *Nematodirus* and *Cooperia* lie in close contact with the mucosa but *Trichostrongylus* spp. larvae and adults form superficial tunnels, causing additional tissue disruption. Lesions are confined to the anterior small intestine and their severity is determined by the density of worms. Surprisingly, malabsorption is not a marked feature of pathogenesis as unaffected parts of the intestine can usually compensate. Consequently, protein digestibility and absorption may be normal. There is, nevertheless, poor retention and utilization of nitrogen due to a protein-losing enteropathy, together with excessive losses from sloughed cells and mucus production. This contributes to production losses and causes hypoalbuminemia and edema in severe cases. Wool growth is affected and the fleece becomes brittle. Mineral absorption is impaired, resulting in reduced skeletal growth, bone density and mineralization.[16] *T. colubriformis* infection reduces the absorption of phosphorus and increases the loss of endogenous phosphorus, thus leading to a phosphorus deficiency.[17] As with abomasal parasitism, the precise reason for the diarrhea associated with these infections is unknown.

Reduced productivity in both abomasal and intestinal parasitism is mostly due to a reduction in appetite that is a constant feature of these infections. In one field study,[18] untreated heifers spent on average 105 min less per day grazing as compared with a matched treated group and their daily herbage intake was 0.78 kg dry matter per day lower. Experimental studies show that inappetence accounts for over 60% of the difference in weight gains between *Ostertagia*-infected and worm-free sheep and cattle. The associated mobilization of adipose tissue gives rise to increased non-esterified fatty acid levels. Voluntary feed intake may be significantly depressed even in parasitized animals showing no clinical signs. The elevated gastrin levels in abomasal trichostrongylid infections impair reticulo-ruminal motility and slow abomasal emptying, leading to a stasis of ingesta and hence a reduction in feed intake.[15] Other, as yet unknown, mechanisms must also be

involved as gastrin levels are not affected by intestinal worms, yet these also depress appetite.

27.1.1.6

CLINICAL FINDINGS

In sheep the two most susceptible age groups are weaner lambs and yearlings. Those over 18 months of age are less prone because of immunity gained from previous infestation. The onset of disease is generally insidious with young animals initially failing to grow satisfactorily and later becoming unthrifty, and lacking in vitality and bloom. If they are observed sufficiently closely their food intake can be seen to be reduced. This may be the full clinical picture in many flocks which are considered to have ‘weaner illthrift'. More severely affected sheep pass dark green, almost black, soft feces which foul the wool of the breech. Lamb and yearling flocks are most seriously affected and a constant mortality begins, a few animals dying each day. The losses are not acute but may eventually exceed 35%. A more dramatic picture occurs when young lambs, especially those in the 6 to 12-week age group, are exposed to sudden pasture challenge with *Nematodirus* spp. There is profuse watery diarrhea and the lambs quickly become dehydrated. Mortality can be high and deaths may start within 2 d of the first observed illness.

In cattle, calves are most vulnerable in their first grazing season, although yearlings and, less often, adults are sometimes affected. They:

- Lose weight rapidly
- Pass soft feces which eventually become very thin and dark green to yellow in color
- Develop a long, dry hair coat
- Become dehydrated with sinking of the eyes in the terminal stages.

Until the last they continue to eat, although the amount of food taken is much below normal. Gross anemia is not evident but the mucosae are pale and dry. Submandibular edema is common, especially in Type II disease. The temperature may be elevated (39.5°C; 103°F) and the heart rate increased (120 bpm) in calves showing dehydration. In the terminal stages the calves become weak and emaciated. Type I ostertagiosis in calves is characterized by high morbidity and low mortality. Although morbidity is low in Type II disease, clinical signs are generally more severe and the prognosis poorer.

27.1.1.7

CLINICAL PATHOLOGY

Fecal egg counts have to be interpreted with caution as they are only well correlated with worm burdens in young animals. Egg counts are however often over 1000 epg (eggs per gram feces) in Type I ostertagiosis. Zero or low epg values may be recorded if:

- The worm burden comprises mainly immature stages (as in Type II disease or some outbreaks of nematodirosis)
- Intestinal damage persists after the worm population has been expelled by immunity or anthelmintic treatment
- Disease is associated with hypersensitivity to incoming larvae.

Different trichostrongylid eggs, other than *Nematodirus*, cannot easily be differentiated and cultures must be made if species determination is necessary.

Plasma pepsinogen estimations are performed routinely in many laboratories as an aid in the diagnosis of ostertagiosis. Elevated values also occur in hemonchosis. The test is difficult to standardize so results from different laboratories cannot be compared but, in calves, levels higher than 3000 iu tyrosine are generally considered to indicate a pathogenic worm burden. Pepsinogen levels decline after effective anthelmintic treatment but do not return to pre-infection values. Older immune cattle may show elevated values when grazing contaminated pasture, even though few incoming larvae are able to establish. Plasma gastrin concentrations reflect the size of the abomasal worm burden in both young and older animals, but currently can only be measured by radioimmunoassay, which limits their field application. Gastrin occurs in several molecular forms and, consequently, test kits have to be validated before use with bovine blood as not all are suitable for this purpose.

1544

1545

Moderate anemia often occurs with hemoglobin levels around 6–8 mg/dL and is more evident in *Cooperia* and *Ostertagia* spp. infestations than in trichostrongylosis where there may be polycythemia. Serum protein concentrations may be as low as 4–5 mg/dL with a marked reduction in serum albumin values.

Species-specific enzyme-linked immunosorbent assay (ELISA) tests are being developed for use with samples from bulk milk tanks but are currently only available for epidemiological research.[19]

27.1.1.8

NECROPSY FINDINGS

Adult worms are found in the abomasum or small intestine depending on the predilection site of the individual species. A total worm count is the critical measure of the degree of infestation. Counts less than 2000 in mixed species of sheep are considered to be light, while counts over 10 000 are heavy, but massive counts of 50 000 and more are often seen. In cattle, burdens of 40 000 and above are seen in Type I ostertagiosis outbreaks (the majority are adults), while in Type II disease worm numbers may be 100 000–200 000, with occasional animals harboring a million or more. In these cases about 90% are in the fourth larval stage. Trichostrongylids are small, translucent and threadlike so even adults can easily evade detection by the naked eye at necropsy. Worm counting therefore involves washing the mucosa, sieving the washings and lumenal contents, re-suspending the residue, taking aliquots and picking out and identifying the nematodes. A more rapid but effective field technique for demonstrating intestinal worms is to:

- Roll a loop of duodenum inside out over a test tube or glass rod
- Immerse this first in aqueous iodine solution (iodine 30 g, potassium iodide 40 g, water 100 mL) for several minutes
- Immerse in a 5% solution of sodium thiosulfate for a few seconds.

The mucosa is decolorized but the brown-stained worms retain their color and are easily seen.[20] Mucosal larval stages have to be released by digesting the tissues with acid-pepsin.

Gross pathological findings are often not striking, apart from the non-specific lesions of emaciation, dehydration, moderate anemia and evidence of scouring. In severe cases, the mucosa of the abomasum and upper small intestine may be hyperemic and swollen, and local lymph nodes enlarged. In ostertagiosis there will be numerous raised nodules which may be discrete or confluent forming a ‘morocco-leather' appearance. Abomasal folds are edematous and diphtheresis may sometimes be apparent. A putrid smell may reflect the growth of microorganisms in the ingesta and estimation of the pH will confirm loss of acidity.

Heavy *T. axei* infection in lambs, calves, and horses causes circumscribed raised plaque-like hyperplastic lesions on the abomasal mucosa, sometimes with an eroded center. Close inspection is needed to see the villous atrophy associated with intestinal *Trichostrongylus* species. Initially this is diffuse but later appears as discrete patches (‘fingerprint lesions').

27.1.1.9

DIAGNOSTIC CONFIRMATION

PGE should not be diagnosed on the basis of a fecal egg count alone. In sheep, a total worm count should be performed whenever possible, preferably with a peptic digest of the mucosa. The results should be considered together with the:

- Clinical signs
- Age of the animal
- Season of the year
- Nutritional status
- Grazing history.

The critical test in an outbreak of disease is the response to treatment. Because the epidemiology of the various species differ, it is important that the main contributing species be determined so that adequate control measures can be taken. In calves, clinical diagnosis can be confirmed by plasma pepsinogen estimation, but this assay is less helpful in adult cattle.

27.1.1.9.1

DIFFERENTIAL DIAGNOSIS

PGE has to be differentiated from other common causes of emaciation and diarrhea in groups of young animals such as:

- Malnutrition
- Copper deficiency (in cattle)
- Coccidiosis (in particular, nematodirosis and coccidiosis occur in lambs of the same age)
- Johne's disease
- Chronic fascioliosis.

27.1.1.10

TREATMENT

Many broad-spectrum anthelmintics are now available that combine high efficiency against larval and adult worms with low toxicity in sheep and cattle. Most however belong to just three major chemical groups:

1. Avermectins/milbemycins, also known as the macrocyclic lactone anthelminthics (MLs), which interfere with nerve transmission by opening chloride channels
2. Benzimidazoles (BZDs)/probenzimidazoles, which bind to tubulin and disrupt nutrient uptake
3. Imidazothiazoles/tetrahydropyrimidines, which act as cholinergic agonists.

Dosage rates and label claims may vary with formulation and from country to country according to local conditions and regulatory requirements. Figures given in this chapter should therefore be regarded only as a general guide.

27.1.1.10.1

Cattle

In cattle, ivermectin, doramectin, and moxidectin are given at 0.2 mg/kg by injection or 0.5 mg/kg as a pour-on formulation. Eprinomectin pour-on 0.5 mg/kg is the compound of choice for adult dairy cattle as it has a nil milk withdrawal period.[21] Albendazole 7.5 mg/kg, febantel 7.5 mg/kg, fenbendazole 7.5 mg/kg, netobimin 7.5 mg/kg, and oxfendazole 4.5 mg/kg are given orally. Levamisole can be used orally or by injection at 7.5 mg/kg or as a pour-on at 10 mg/kg.

Sustained release intraruminal devices (‘boluses') for use in cattle provide extended periods of protection. For example, fenbendazole is released for up to 140 d from one bolus, while a biodegradable bolus releases morantel tartrate for at least 90 d. There are also pulse-release boluses containing oxfendazole, which release five or six anthelmintic doses at 3-week intervals.

27.1.1.10.2

Sheep

In sheep, the dose rate for ivermectin, doramectin, and moxidectin (which are given orally or parenterally) is 0.2 mg/kg. Dose rates for the BZDs (given orally) are: albendazole 5 mg/kg, febantel 5 mg/kg, fenbendazole 5 mg/kg, netobimin 7.5 mg/kg,

mebendazole 15 mg/kg, and oxfendazole 5 mg/kg. Levamisole can be used orally and parenterally at 7.5 mg/kg. Morantel citrate monohydrate is also used as a drench in sheep. Pour-on formulations are not used in sheep as the wool grease does not allow absorption through the skin. Intraruminal devices for use in sheep have been developed which release albendazole or ivermectin over 100 d.[22,23]

27.1.1.10.3

Goats

Goats metabolize some anthelmintics more rapidly than do sheep and elevated dose rates are sometimes required to obtain a satisfactory level of control. Even then, there may be more surviving worms and consequently anthelmintic resistance tends to develop much more quickly in goats than sheep. Examples of special dose-rates for goats include: 1545 albendazole 10 mg/kg and levamisole (which should be used with caution in goats) 12 1546 mg/kg. Ivermectin can be given at the normal dose-rate of 0.2 mg/kg.

27.1.1.11

CHOICE OF ANTHELMINTIC

The choice of anthelmintic depends on a number of considerations. Anthelmintic resistance is a real or emerging problem in many sheep-rearing areas. Side resistance occurs within chemical groups and multiple-resistant strains have been reported. This can impose a severe constraint on product choice Other factors include:

- Price
- Safety (including meat and milk residues and effect on environment)
- Ease of administration
- Spectrum of activity.

Older products were most active against adult worms, but many now have activity against larval stages. Fewer however have consistently high efficacy against hypobiotic larvae and care is needed in selecting a suitable product to treat or prevent Type II disease. Products with claims for this purpose at stan-dard dose-rates include avermectins/milbemycins, albendazole, fenbendazole, oxfendazole, and thiophanate, while netobimin is active at an elevated dose-rate (20 mg/kg). The benzimidazoles are ovicidal, which may be beneficial if stock are moved to a new pasture after treatment. Animals with PGE may also be harboring other parasites The avermectins/milbemycins have a very broad spectrum of activity including some ectoparasites but are inactive against cestodes and trematodes.

Some broad-spectrum BZDs are effective against cestodes and one, albendazole, is also active against mature *Fasciola hepatica*. The avermectins/milbemycins are excreted in the feces and may affect insects colonizing the dung pat.[24] The environmental impact of this has probably been overstated as only a small proportion of the fecal mass on a property will contain anthelmintic, allowing adequate refugia for maintenance of insect populations. This class of compound should however be used with caution if there is concern that beneficial insects may be vulnerable, for example, dung-beetles in some arid zones.

Novel methods for increasing drug availability and anthelmintic effect within the body are under investigation[25] and should be adopted by veterinarians as they become available. There is uncertainty when, or even if, new chemical classes will become commercially available for nematode control and so it is essential that existing products are used as efficiency as possible to extend their effective life. Using measures which maximize the potency of anthelmintics can slow the onset of resistance and increase efficacy against partially resistant strains. The efficacy of the BZDs and orally administered avermectins depends on their residence time in the rumen and some simple measures can be taken to increase this. Correct drenching procedure (gun tip over tongue and drench dispensed directly into esophagus) will avoid stimulation of the esophageal groove reflex[26] and ensure that the dose does not bypass the rumen. As there is an inverse relationship between feed intake and rumenal residency time, a reduction in feed intake (e.g. by penning) for 24 h before prophylactic drenching retards transit time and significantly enhances the activity of BZDs and ivermectin. With BZDs, drug residency time in the rumen can be further increased and efficacy enhanced by dividing the dose and giving it at 12- or 24-hour intervals. This principle is reflected in medicated lick-blocks and intraruminal boluses which provide daily low-level BZD doses.

Continued protection must be given to animals after treatment for clinical PGE. Irrespective of the drug used, treated animals should be moved to a clean paddock (i.e. one not contaminated with large numbers of infected larvae) which provides an adequate plane of nutrition. The ovicidal action of the BZDs is particularly useful if animals are being placed on very clean areas such as cereal stubble. However, it is probably of lesser importance on many farms where residual pasture contamination is always present. If clean pasture is not available, protection can be provided by use of an anthelmintic with persistent activity against incoming larvae. In cattle, ivermectin provides up to 21 days' protection against *O. ostertagi* and up to 14 days' against *Cooperia* spp. Corresponding figures for eprinomectin are: 28 and 21 d; for doramectin: 35 and 21 d (by injection) and 35 and 28 d (pour-on); and for moxidectin: up to 28 days against *O. ostertagi*. The

persistent anthelmintic effect of avermectins in sheep is much shorter and there is probably little useful effect against intestinal trichostrongylids.

Moxidectin given by injection has a label claim for 5 weeks protection against *O. circumcincta* and 2 weeks against *T. colubriformis*.

27.1.1.12

CONTROL

Control measures are aimed at reducing pasture contamination in order to minimize the uptake of infective larvae, thereby preventing disease and allowing optimal productivity. The cost of any program and treatments must accord with potential economic benefits. Where individual animals are valuable, labor-intensive strategies may be justified. Many husbandry systems however will support only low input solutions and treatments may only be feasible when animals are handled for other management procedures. Epidemiological patterns differ for each worm species and vary considerably from region to region, with subtle variations often occurring from locality to locality. It is therefore beyond the scope of this text to make specific recommendations for control but it is possible to describe general principles which can be adapted to local needs.

Knowledge of local epidemiology is a necessary prerequisite for designing a control program. In particular, the animals providing the major source of contamination should be identified, the period of development from egg to infective larvae and the availability of infective larvae throughout the year known. It is essential to formulate clear and precise control objectives, otherwise much time and expense can be wasted. Management may have to be adjusted to aid control. On organic farms, where anthelmintic usage is greatly restricted, worm control may be a major factor in determining stocking density and grazing management. Often, control measures are aimed primarily at protecting the most susceptible group, that is, young animals up to 18 months of age exposed to infestation for the first time.

Anthelmintic resistance is an important consideration influencing the choice and intensity of control measures. Even if economically justified, frequent routine treatments impose strong selection pressure on worm populations and encourage the development of resistant strains. As only three major chemical groups are currently available for the treatment of gastrointestinal and pulmonary nematodes, it is imperative that their usefulness is conserved for as long as possible. Many anecdotal field reports of resistance are erroneous, the problem being one of reinfestation or incorrect anthelmintic usage. Nevertheless, resistant and multiresistant strains are already prevalent in many sheep-rearing areas.[27] So

far, there have been few reports from cattle. The following recommendations have been made to slow the onset of resistance[28]:

1. Use an effective drug in the most efficient manner:
    - Check fecal egg counts regularly to confirm that chosen products remain effective
    - If a worm population is already partly resistant to a compound, continued use of products based on that chemical group will endanger the health of the animals and reinforce the resistance.

1546

1547

2. Do not underdose (this may encourage resistance):
    - Weigh each animal or the heaviest individuals in a group
    - Comply with all label recommendations
    - Ensure good maintenance and calibration of dosing equipment.
3. Use the minimum number of doses needed to maintain health:
    - Strike a balance between encouraging resistance by treating too intensively and allowing pasture contamination to rise to unacceptable levels.
4. Use sound epidemiological principles:
    - Utilize an integrated approach to worm control which maximizes the potential of management techniques and minimizes reliance on anthelmintics.
5. Rotate the chemical group annually (to ensure that worms are exposed to compounds with a different mode of action each year):
    - Remember there is no benefit in rotating compounds within a chemical group, nor in using a group already rendered ineffective by anthelmintic resistance.
6. Avoid introducing resistant worms onto a property (obvious, but often overlooked):
    - Place all new stock into quarantine and treat with an effective compound
    - Do not graze goats on sheep pastures (as caprine worm populations often have a higher prevalence of resistance genes).

7. Make sure that the farmer is aware of the problem and the consequences of anthelmintic resistance.

The concept of maintaining parasite refugia is assuming greater prominence as a means of conserving anthelmintic efficicacy in modern control strategies. The theoretical background and clinical application are discussed in detail in Abbott et al. (2004) – see Review Literature below. Worms ‘in refugia' are those not exposed to anthelmintic when the flock is treated. They thereby escape selection pressure for resistance. When the flock subsequently becomes re-infected, the genetic material from parasites surviving treatment will be diluted by susceptibility genes from worms ‘in refugia' at that time. This slows the rate at which resistance develops and extends the period over which the drug maintains clinical efficacy on the farm. The refugia concept is best illustrated by an example. In cooler temperate climates, infective *Ostertagia* larvae overwinter on grass in large numbers but most *Haemonchus* larvae succumb to the cold. If ewes are dosed during the winter to eliminate the periparturient egg-rise, only a small proportion of the *Ostertagia* population (those in the animal) are exposed to the anthelmintic, while the remainder (those on the pasture) are ‘in refugia'. In contrast, a high proportion of the total *Haemonchus* population is exposed to the drug (as there are few larvae ‘in refugia' on the pasture) and in consequence there is an enhanced risk of anthelmintic resistance developing. From this viewpoint, therefore, it could be beneficial in the longer term to withhold the winter treatment from some ewes. This would ensure that the majority of eggs subsequently dropped onto the pasture are produced by susceptible worms. Similarly, dose and move systems encourage resistance as all eggs dropped onto the new pasture are from worms that have survived treatment. It could therefore be advantageous to use a short-acting drug and to delay the move. This would ensure that the animals acquire a small burden of susceptible worms before the move. These strategies involve obvious inherent risks and all aspects of a particular situation must be carefully considered before implementation.

Protocols for detecting anthelmintic resistance in a herd or flock are available.[29] The fecal egg-count reduction test can be performed easily without sophisticated equipment. The epg value should be reduced by 95% or more, but false negatives may be obtained with BZDs (if female worms are sterilized but not killed) and false positives with levamisole (if large numbers of mucosal larvae present at the time of dosing survive treatment). Laboratory tests include egg-hatch assays for BZDs and larval development

tests for avermectins and levamisole. Improved assays, including polymerase chain reaction (PCR)-based tests for BZDs, are being developed.

The Principles of Control generally fall into three categories[30]:

1. Preventive
2. Evasive
3. Diluting.

Preventive measures are those that place livestock on clean pasture or that use early season chemoprophylaxis to ensure clean grazing later in the season.

Evasive strategies are those in which pasture contamination is allowed to build up naturally but susceptible stock are moved on to clean grazing before pathogenic numbers of infective larvae have accumulated.[31] An anthelmintic dose can be given at the time of the move. This ‘dose and move' system is effective and reduces anthelmintic dosage very considerably. It may however encourage resistance as discussed in the previous paragraph.

Diluting systems reduce the effective stocking density of susceptible animals by grazing them alongside non-susceptibles (older immune stock or alternative species). In cow-calf systems, for example, adults produce at least four times as much feces as their calves but their average egg count is typically no more than 15 epg. The number of trichostrongylid eggs and the subsequent accumulation of infective larvae on the herbage will therefore be considerably smaller than if the pasture was fully utilized by calves alone.

In cool temperate regions, control measures can take advantage of the fact that overwintered larvae die away in early summer. Hay or silage pastures therefore provide safe grazing after the grass has been cropped. Alternatively, suppressive anthelmintic therapy over the first 90–100 d of the grazing season will prevent overwintered larvae establishing in the host and thereby stop the subsequent accumulation of infective larvae on the herbage. This strategy is very effective on set-stocked permanent calf paddocks provided that no untreated animals are introduced. The required effect can be obtained by use of an intraruminal anthelmintic device administered around the time of spring turnout or by giving two or more doses of an anthelmintic with prolonged activity against incoming larvae. As the object is to prevent egg excretion, the required treatment interval is calculated by adding the length of the protective effect (which varies with the product) and the prepatent period of the worms (about 3 weeks). Ivermectin given 3, 8, and 13

weeks after turnout and doramectin given at turnout and 8 weeks later are very effective for this purpose, as are the intraruminal boluses listed earlier.

Controlled field studies have demonstrated significant weight-gain advantages from this approach but, as with cattle lungworm, there is concern that the level of immunity acquired during the first grazing season may be reduced. Usually this is of no clinical consequence but results from an epidemiological survey of 87 farms in Holland suggest a beneficial relationship between immunity to nematodes gained during the first grazing season and the growth rate of cattle during their second grazing season.[32] It seems that optimal protection has to balance risk of production losses in first and subsequent grazing seasons but there is currently no objective way of doing this.[33] One suggestion is that rumen boluses would be better employed if used to provide anthelmintic cover in the second half of the grazing season when pasture contamination is high (‘metaphylaxis'). Good immunity would be assured but the growth rate advantage may be inferior to that obtained with the early season prophylaxis described earlier.[34] If cattle have been exposed to high pasture challenge in the autumn, they should be dosed with a product active against hypobiotic larvae at housing or during the winter to prevent Type II ostertagiosis. In countries where *Dictyocaulus viviparus* is a problem, control of PGE and lungworm must be integrated.

1547
1548

Elimination of the periparturient egg rise is the most important feature of worm control in sheep. Ideally, ewes should be dosed towards the end of gestation and again 1 month after parturition with a product active against hypobiotic larvae. Lambs should be dosed at weaning and if possible moved to clean pasture. In most cases, further treatments will be necessary to maintain health until marketing but these should be kept to a minimum. The number will depend on the stocking density, initial pasture contamination and weather. A compromise has to be struck between an acceptable level of disease control and the risk of inducing anthelmintic resistance. Fecal egg counts can be used to check the adequacy of the dosing interval and the efficacy of the treatments.

Control of *Nematodirus* differs from that of other forms of PGE because the ewe is not a source of contamination. The simplest form of control is to avoid putting the new lamb crop onto pasture contaminated by the previous year's lambs. Often however this is not feasible and prophylactic anthelmintic doses at 3-week intervals are necessary to cover the limited period of risk (May to early June, for example, in Scotland). Waiting for the first clinical signs before starting treatments is not recommended as deaths can occur very quickly. The precise timing of the egg hatch varies from year to year according to prevailing weather conditions, but forecasting systems are in operation in some countries.

In warm temperate regions, PGE control strategies are more difficult to design as animals graze all year round. The main transmission period is late winter and early spring. Treatment of beef cattle at weaning and once or twice at locally determined intervals thereafter is often sufficient to reduce pasture contamination.[35] In sheep, an effective program is to dose lambs at weaning and move them onto safe pasture. Two or three subsequent treatments at 8-week intervals may be needed. In summer rainfall areas, *Haemonchus* is an additional hazard and systems have to be designed to combat this as well as other gastrointestinal worms.

In regions with a prolonged dry season, larvae will be killed on the ground and, providing there are no foci of infection around water holes etc., a single strategic anthelmintic dose at this time with a product active against hypobiotic larvae may be more effective at maintaining low pasture contamination around the year than repeated dosing throughout the wet season. This single dose may, however, apply greater selection pressure for resistance, since the whole parasite population is exposed to the drug and survivors are likely to carry resistance genes.

Reduced reliance on anthelmintics can be achieved in a number of ways. For example, alternate grazing with sheep and cattle can be employed to good effect. In Australia, the number of anthelmintic drenches can be substantially reduced by alternation at 2–6 month intervals.[30] In northern Britain annual stock rotations, sometimes with an arable crop grown in the third year, have been successfully evaluated. Host specificity however is not absolute and calves can become infected with *N. battus*. If this happens, they may drop sufficient numbers of eggs to cause clinical problems in lambs the following year. Lambs have also been known to succumb to *T. axei* on calf paddocks. An exciting future prospect is the use of nematophagous fungi. Orally administered fungal spores produce hyphae in the feces that trap and kill nematode larvae. Field experiments show that pasture contamination can be substantially reduced in this way.[36] Feed supplementation to enhance host resilience and resistance to infection, vaccination and future prospects for breeding lines of sheep with innate host resistance are described under *Haemonchus*.

Breakdowns in control programs are usually due to:

- Failure to prevent worm egg-output at times critical to the accumulation of infective larvae on the pasture.

- Failure, after treatment, to move animals on an already contaminated pasture to a clean environment
- Use of an insufficient dose or incorrect anthelmintic
- Failure to repeat treatment or repeating treatment at overlong intervals at times of high risk
- Failure to appreciate that not all anthelmintics kill all immature stages, particularly hypobiotic forms
- Introduction of susceptible sheep from a worm-free environment into a high risk area
- Failure to protect young animals adequately.

27.2 ## Hemonchosis in ruminants

27.2.1 ### ETIOLOGY

Sheep, cattle, and goats are all affected by species of the nematode genus *Haemonchus*, which is closely related to the other trichostrongylids of ruminants. *H. contortus* is the species most commonly found in sheep and goats, but *H. placei* is the usual species in cattle. Molecular studies have confirmed that these are distinct taxa.[1] Even so, cross-infection may occur when small ruminants and cattle graze together but the infestations are usually of lesser severity Another abomasal trichostrongylid, *Mecistocirrus digitatus*, occurs in sheep, cattle, and buffalo in the Orient and in Central America, causing a disease very similar to hemonchosis.

1548 1549

27.2.1.1 #### Synopsis

27.2.1.1.1 ##### Etiology

The nematode parasite *Haemonchus contortus* in sheep and goats and *H. placei* in cattle.

27.2.1.1.2 ##### Epidemiology

Female worms produce large numbers of eggs; infective larvae develop rapidly in warm wet conditions; dangerous levels of pasture contamination can therefore accumulate rapidly.

27.2.1.1.3 ##### Signs

Acute: sudden death, anemia; *Chronic*: wasting, anemia, anasarca.

27.2.1.1.4

Clinical pathology

Anemia, hypoproteinemia; often high fecal egg count.

27.2.1.1.5

Lesions

Anemic carcass; abomasal mucosa hyperemic with many red-colored worms.

27.2.1.1.6

Diagnostic confirmation

'Barber's pole' appearance of female worms (if fresh).

27.2.1.1.7

Treatment

All modern broad-spectrum anthelmintics; also, closantel, rafoxanide, nitroxynil, disophenol and some organophosphates; care needed in selection as resistant and multiresistant strains of *H. contortus* occur.

27.2.1.1.8

Control

Strategic dosing schemes using broad-spectrum anthelmintics; closantel or disophenol can be used to reduce dependence on broad-spectrum products.

27.2.2

LIFECYCLE

Haemonchus contortus inhabits the abomasum. It is easily seen as it is 1–2.5 cm long and a little stouter than most other trichostrongylids. Adult males are homogeneously red but the females have a spiral red and white appearance as the intestine and uterus intertwine. Adult *H. contortus* are prolific egg layers. Egg production increases until maximum output is reached 25–30 d after infection, after which individual females lay up to 10 000 eggs per day for several months. The egg hatches and passes through two non-infective larval stages in 4 d under optimal conditions but in less suitable environments, this period may be prolonged. For example, in Scotland the shortest time required for development from egg to third stage larva is 2 weeks but development takes a great deal longer over most of the year. Infective larvae migrate away from fecal pellets, some traveling 90 cm in 24 h. More than 90% however are found within 10 cm of the fecal mass and this number decreases logarithmically as the distance increases.[2] Motility is greatest in hot, moist conditions. Larvae are susceptible to desiccation and do not withstand cold temperatures well.[3] Where hostile external conditions occur regularly, such as winter in temperate regions or the dry season in some

tropical climates, *H. contortus* larvae on pasture are conditioned at the appropriate time to become hypobiotic after uptake by a host. Transmission occurs when the host ingests infective larvae while grazing. After developing through the fourth larval stage in the abomasal glands, the adult worms emerge to commence egg laying in about 18 d after infection. Hypobiotic larvae resume their development so that egg laying is coordinated with the start of spring or the wet season.

The lifecycle of *H. placei* is similar except that the first eggs do not appear in the feces of cattle until the 26th day after infestation, rising to a peak at 6–7 weeks and declining rapidly to low levels by 11–14 weeks.

27.2.3 EPIDEMIOLOGY

The epidemiology of hemonchosis is largely determined by the high fecundity of the female worms and the speed with which infective larvae can develop in warm, humid conditions. Thus, when conditions are favorable, large numbers of infective larvae can accumulate very rapidly on pasture. Opportunities for transmission are however restricted by the susceptibility of the larvae to desiccation and cold.

Hemonchosis is an important disease of sheep, goats, and cattle in all but the coldest regions. The greatest economic impact is seen in sheep in tropical and warmer temperate countries, especially where there is good summer rainfall. It is not uncommon for serious outbreaks to occur in cooler climates during periods of high humidity in summer. The disease is uncommon in semi-arid regions unless there are opportunities for transmission to occur in, for example, irrigation schemes. In sheep, losses occur mostly in lambs, especially those recently weaned, but yearlings and mature sheep may also be affected. Goats of any age are susceptible but their browsing habit may protect them from the heaviest sources of contamination. Dairy calves are the most commonly involved group amongst cattle but steers and other young cattle up to 3 years of age may also be affected.

Predisposing causes for hemonchosis include overcrowding, lush pasture, hot and humid climatic conditions and a low plane of nutrition. Disease can be precipitated in several ways. An important causal mechanism in sheep is when lambs, that may be in excellent condition on good grazing, are overcome by a sudden massive wave of pasture contamination. Sheep in poor condition may be clinically affected by worm burdens too small to harm an otherwise healthy animal. Outbreaks of disease may occur in sheep overwintered indoors if large numbers of hypobiotic larvae mature simultaneously.[4] Cattle harboring subclinical infestations while on a good plane of nutrition may show clinical signs if the pasture

subsequently fails because of drought or overgrazing. In goats, *Trypanosoma congolense* infection has been shown to increase the susceptibility to *H. contortus*.[5]

The climatological conditions that permit the development of hemonchosis in sheep have been the subject of much research. Bioclimatographs have been produced for many different geographic areas. In regions with narrow diurnal temperature fluctuations, outbreaks are likely during months with a mean maximum temperature of 18°C (64°F) and more than 5.25 cm rain.[6] In areas with regular summer rainfall, larval availability increases from late spring to reach maximum levels by late summer to early autumn and quickly declines in winter. A similar trend, but with fluctuating larval numbers, occurs in areas with more variable rainfall patterns.

The self-cure phenomenon is a sudden naturally occurring expulsion of adult *H. contortus* which may also, although not invariably, eliminate incoming larvae. In some areas, this may be associated with changes in the pasture[7] but more often it occurs in sheep when a large uptake of infective larvae is superimposed on an established worm burden in a sensitized animal. Self-cure may also expel existing *Ostertagia circumcincta* and *Trichostrongylus axei* from the abomasum and *Trichostrongylus* spp. from the small intestine. Strain or breed differences occur and a genetic resistance operating primarily against worm establishment and probably controlled by the immune response has been reported.[8] There is no complete self-cure with *H. placei* in calves but after an initial infection there is a rapid decline in egg laying, adults are expelled and subsequent larval development is retarded. Immunity is much stronger in calves than in sheep.

27.2.4 PATHOGENESIS

Vigorous bloodsucking by both fourth-stage larvae and adults is the main factor differentiating the pathogenesis of *H. contortus* from that of other abomasal nematodes. The histological changes and biochemical sequelae associated with *Ostertagia* infections also occur in hemonchosis but in addition a hemorrhagic anemia evolves due to the daily loss of around 0.05 mL of whole blood per worm. The course of the disease depends on the numbers of worms present and the ability of the animal to compensate for acute or chronic losses of plasma proteins, hemoglobin and other blood constituents. In continuing infections, the increased rate of red cell production is maintained at the expense of the animals' iron stores and a state of iron deficiency occurs. Death may be acute and result purely from blood loss or may be more gradual and accompanied by weight loss, anemia, and hypoproteinemia.[9] Poor growth in young lambs can result from a reduction in their ewes' milk production.

Susceptibility to hemonchosis varies with breed. Those with superior resistance include the Scottish Blackface, Red Maasai, Florida Native, St Croix, and Barbados Blackbelly, whereas the Hampshire Down is relatively susceptible. Individuals within a flock also vary in vulnerability. This natural resistance to infection is heritable.[10]

The role of nutrition in modifying the pathogenesis of hemonchosis in lambs is undergoing intense investigation. There is experimental evidence that lambs on a high protein diet are better able to withstand *H. contortus* infestation.[11] There are considerable breed differences; in some cases, animals with a higher protein intake mount a more effective immune response, in others they are better able to tolerate and compensate for the blood losses associated with the infection.[12]

27.2.5 CLINICAL FINDINGS

Hemonchosis causes heavy losses due to animal deaths and reduced production. Lambs and young sheep are commonly affected by the acute form of the disease. Often only a few individuals will be seriously affected but in very severe outbreaks, a large proportion of the flock may suffer if not treated.[13] Animals may be found dead without premonitory signs having been observed. The mucosae and conjunctivae of such sheep are always extremely pale. More chronic cases show lethargy and muscular weakness, pallor of the mucosae and conjunctivae, and anasarca, particularly under the lower jaw and to a lesser extent along the ventral abdomen. Affected sheep are often noticed for the first time when the flock is being driven: they lag behind, breathe faster, have a staggering gait and often go down. Some sheep may die as a result of exercise but most can rise and walk a little further after rest. Grazing animals lie down a good deal of the time, often around the water troughs; the energy needed to walk and eat appears to be lacking. Most affected sheep show constipation rather than diarrhea. There is a loss of body weight and a detrimental effect on wool growth and quality. In sheep with the chronic condition, there may be extreme weight loss during the dry season, even though larval uptake is negligible at this time. Sheep not fatally affected develop a break in the wool and the fleece may be lost at a later date.

In calves, the disease is characterized clinically by severe anemia and anasarca. Heavy infestations occurring in summer may not manifest clinically until winter when the plane of nutrition declines.

27.2.6

CLINICAL PATHOLOGY

As *Haemonchus* is a prolific egg layer, fecal egg counts tend to be high (10 000 epg in severe cases), but it must be remembered that low egg counts may be encountered in the early part of the evolution of the disease when the bulk of the pathogenic worms are in the larval stage. There is a significant rise of abomasal pH soon after infection accompanied by increased plasma pepsinogen and gastrin concentrations.[14] Worm counts and hemoglobin levels are correlated.

27.2.7

NECROPSY FINDINGS

Gross necropsy findings include severe anemia, gelatinization of fat deposits, general anasarca and the presence of large numbers of readily visible *H. contortus* or *H. placei* in the abomasum. If the cadaver is fresh, the worms may still be attached or swimming actively in the ingesta, but a careful search may be necessary if the animal has been dead for some time. The abomasal wall is hyperemic and blood clots may be present in the mucosa. Small ulcerations may be present where adult worms have been attached. The abomasal contents usually have a distinct brownish color due to the presence of free blood.

27.2.8

DIAGNOSTIC CONFIRMATION

In mixed infections, eggs of *Haemonchus* spp cannot be easily differentiated from those of many other gastrointestinal nematodes. Identification and quantification therefore depend on counting larvae in fecal cultures, a procedure not readily applicable in routine diagnosis. The number of worms required to depress hemoglobin levels varies with the weight of the sheep. In Merino sheep up to 20 kg, a hemoglobin level of 10.5 g/dL has been associated with 112 worms and 8.0 g/dL with 355 worms. However, in sheep over 50 kg, 355 and 1259 worms were required to give similar values.[15] At necropsy, counts of 3000 *H. contortus* in lambs and 9000 in adult sheep are usually associated with heavy mortalities.

27.2.8.1

DIFFERENTIAL DIAGNOSIS

27.2.8.1.1

Sheep

Other causes of sudden death, such as lightning strike, snakebite, anthrax or enterotoxemia are often suggested by the farmer and can only be differentiated by necropsy. The other common causes of anemia include:

- Fasciolosis
- Eperythrozoonosis
- Nutritional deficiencies of copper and cobalt
- Diarrhea is a much more prominent sign in other parasitic infestations, particularly trichostrongylosis and coccidiosis.

27.2.8.1.2

Calves

Hemonchosis has to be differentiated from:

- Babesiosis
- Anaplasmosis
- Coccidiosis
- Hookworm infection
- Other causes of anemia including heavy infestations with sucking lice, hemolytic anemia caused by drinking large quantities of cold water, the ingestion of rape, kale, and chou moellier, bacillary hemoglobinuria and leptospirosis.

27.2.9

TREATMENT

All the broad-spectrum ruminant anthelmintics are effective against *Haemonchus* provided that resistance has not developed to that chemical group. Ivermectin given by injection provides up to 14 days' protection against re-infection with *H. placei* in cattle and up to 10 days' protection with *H. contortus* in sheep. Moxidectin, by mouth or by injection, gives up to 35 days' persistent activity against *H. contortus*.[16] Some compounds active against *Fasciola hepatica* that bind to plasma proteins are also active against blood-sucking nematodes such as *Haemonchus* and are useful for use where resistance to broad-spectrum products is a problem. These include closantel, rafoxanide and nitroxynil. Closantel and disophenol, another narrow-spectrum product, exert a persistent protective effect in sheep for up to 4 weeks. With closantel, this period can be extended by reducing feed intake for 24 h before treatment to enhance the uptake of the drug.[17] Organophosphate anthelmintics are available in some localities for use against resistant strains. *H. contortus* strains resistant to benzimidazoles (BZDs), levamisole, morantel, naphthalophos, ivermectin, moxidectin, and

closantel have been reported and strains with multiple resistance to two or more of these chemicals are common in some areas.[18,19] To date, resistance problems have not been reported with *H. placei*.

27.2.10 CONTROL

In sheep flocks, a late winter treatment will remove hypobiotic larvae before they resume development and start to shed eggs onto the pasture. Where winters are severe enough to kill most of the free-living stages, this single drench will considerably reduce subsequent pasture contamination but may also expose the parasite population to a high level of selection pressure, thereby encouraging the onset of resistance. In areas where larvae overwinter on pasture and infest lambs in early spring, further treatments may be needed in spring and early summer to prevent an accumulation of infection in the sheep and a subsequent build-up of pasture contamination.

If no routine control is practised and pasture contamination becomes high, stock should be dosed and moved to clean grazing areas. If this is not possible, anthelmintic cover must be provided by using a sustained acting compound such as closantel, disophenol, or moxidectin. Sustained release intraruminal devices for sheep containing ivermectin or albendazole are used in some countries.[20] In cattle, protection can be given by avermectin/milbemycin treatment or an intraruminal bolus. If none of these are available or economically justified, other broad-spectrum compounds can be given at 2 to 4-week intervals throughout the risk period.

In the wet tropics, a rotational grazing system has been devised based on the observation that infective *H. contortus* larvae are relatively short lived at high ambient temperatures. Small ruminants are grazed sequentially for up to 4 d on a series of suitably sized small plots, each of which is rested for at least 30 d before re-use.[21] Where fencing is not feasible, a similar rotation can be based on a planned tethering system. This approach is not effective in temperate areas however as under these conditions infective larvae have a prolonged lifespan and substantial numbers will still be present when the grass needs to be re-grazed.

Frequent treatments with broad-spectrum anthelmintics can lead to the development of anthelmintic resistance. Control programs have therefore been devised which reduce dependence on broad-spectrum products by utilizing the sustained action of closantel against *H. contortus*. Treatment with closantel in late winter kills hypobiotic larvae and, subsequently, overwintering larvae from the pasture as they are ingested. In the case of ewes

which lamb in early spring, further treatments in late spring and late summer can provide excellent cover. As closantel has no effect against *O. circumcincta* or *Trichostrongylus* spp., strategic treatments with a broad spectrum compound must also be incorporated into the scheme. Lambs can be treated with closantel and a broad-spectrum compound when they are about 12 weeks of age and again 12 weeks later. This procedure has been desig-nated the 'Wormkill' program and variations on the theme, tailor made for particular localities and management systems, have been widely accepted in parts of Australia where BZD-resistant strains of *H. contortus* are prevalent.[22] Use over a number of years has reduced *H. contortus* to negligible levels on many farms, but closantel resistance is starting to emerge.[23] Disophenol has been used for a similar purpose in other areas.[24]

A BZD-resistant *H. contortus* population on a farm is unlikely to revert to susceptibility even if this class of compound is withheld from use for a protracted period.[25] This is due to the genetic mechanisms involved in the selection process.[26] In a novel and partly successful attempt to find a solution to this problem, resistant *H. contortus* were diluted experimentally by spraying a susceptible strain onto pasture at different times in the grazing calendar.[27] This approach however raises obvious ethical questions.

The FAMACHA system for managing hemonchosis is a more easily applied field technique for reducing selection pressure for anthelmintic resistance. It was developed in South Africa[28] and recently validated in the USA.[29] It utilizes the fact that a high proportion of the total parasitic *H. cortortus* population is found in just a small proportion of individual sheep within a flock. These will be the most anemic animals and will be shedding the greatest number of eggs onto the pasture. They are identified by comparing the ocular conjunctivae of each animal against a graded color chart. By confining treatment to these individuals, the general health of the flock is maintained with fewer anthelmintic doses, while pasture contamination is substantially reduced and is largely derived from untreated sheep.

Natural resistance to gastrointestinal nematodes can be enhanced by breeding from rams selected for low fecal egg-counts. This provides a feasible method of reducing reliance on chemical control. Heritability for this trait, which is mediated by IgA-induced retardation of worm growth, is between 0.2 and 0.4. Selection for genetic resistance may however reduce capacity to select for other production attributes in some circumstances.[10]

Vaccination is an attractive future possibility and considerable progress is being made in this direction. An experimental molecular vaccine based on an *H. contortus* gut membrane

antigen has been shown to reduce fecal egg counts by 90% and worm numbers by 72–80%.[30] Young lambs can be protected by the passive transfer of colostral antibodies from vaccinated ewes.[31] There is no cross-immunity with other gastrointestinal nematodes and so anthelmintic therapy will still be necessary if these pose a health risk.

In poorer farming regions, the routine use of modern anthelmintics or vaccination may be prohibitively expensive and alternative sustainable methods are being sought.[32] This may involve identifying more resistant indigenous breeds to replace more productive but more vulnerable imported breeds. Another option is the provision of a supplementary diet containing locally available protein. This enhances the ability of breeds more susceptible to *H. contortus* to withstand the pathogenic effects of infection[12] and may be economically feasible in some agricultural systems. Some native forages contain substances, for example tannins, that are naturally deleterious to gastrointestinal worm populations.[33] Alternate or mixed grazing systems can also be employed.

27.2.11 # Bunostomosis (hookworm disease) in ruminants

27.2.11.1 ## Synopsis

27.2.11.1.1 ### Etiology

Nematodes of the genus *Bunostomum* and related hookworms.

27.2.11.1.2 ### Epidemiology

Transmission is generally by skin penetration and is favored by warm, humid conditions.

27.2.11.1.3 ### Signs

Anemia, diarrhea, and anasarca.

27.2.11.1.4 ### Clinical pathology

Eggs and occult blood in feces, anemia, hypoproteinemia; none of these signs is specific.

27.2.11.1.5 ### Lesions

Red worms attached to mucosa of small intestine, nearby ingesta often blood-stained.

27.2.11.1.6 ### Diagnostic confirmation

Necropsy is only certain method.

27.2.11.1.7 ### Treatment

Most modern broad-spectrum ruminant anthelmintics are effective as well as those narrow-spectrum compounds that bind to plasma protein.

27.2.11.1.8 ### Control

General preventive programs for parasitic gastroenteritis are also effective against hookworm.

27.2.11.2

ETIOLOGY

All farm animals other than horses harbor hookworms. The main species are:

- **Cattle:** *Bunostomum phlebotomum* is the most widespread but *Agriostomum vryburgi* may occur in cattle in Asia and South America
- **Sheep:** *B. trigonocephalum* is found worldwide while *Gaigeria pachyscelis* occurs in India, Indonesia, South America and Africa.

Additionally, *Globocephalus* spp. occur in pigs but are rarely of clinical importance.

27.2.11.3

LIFECYCLE

Hookworms are reddish-colored nematodes, 1–2.5 cm long, and inhabit the small intestine of their hosts. The females are prolific egg layers and the lifecycle is direct. The eggs hatch and two free-living, non-parasitic larval stages follow, which are very susceptible to desiccation. An infective larva is produced in about 1 week under favorable conditions. Transmission is by skin penetration alone in the case of *G. pachyscelis* but *Bunostomum* spp. larvae can enter the body via the skin or the mouth.[1] After cutaneous penetration, larvae:

- Enter the bloodstream
- Are carried to the heart and lungs
- Enter the alveoli where the fourth-stage larvae develop
- Pass up the air passages to the pharynx
- Are swallowed
- Reach the small intestine.

Ingested larvae penetrate the intestinal wall and return to its lumen without further migration. In *B. trigonocephalum* infestations, the fourth-stage larvae reach the intestine in about 11 d and egg-laying adults are present about 7 weeks after infestation. The prepatent period in *B. phlebotomum* infestations is about 8 weeks and in *G. pachyscelis* 10 weeks.

27.2.11.4

EPIDEMIOLOGY

The chances of infestation occurring by percutaneous entry are greatly enhanced when the surroundings are wet, and this, together with the susceptibility of the larvae to desiccation, leads to a higher incidence of the disease in humid subtropical or warm temperate countries such as the southern United States, Africa, northern Australia, and parts of Europe. Heavy infestations of sheep or cattle are uncommon in cooler temperate countries but do occur occasionally when animals are winter housed in dirty surroundings with insufficient bedding. Immunity to *B. phlebotomum* in cattle appears to develop with age and animals affected one year appear to be completely immune the next. Calves 4–12 months of age are most commonly affected and the degree of infestation is always greatest in the winter months.

27.2.11.5

PATHOGENESIS

Hookworms are active bloodsuckers and cause severe anemia in all animal species. Total worm numbers as low as 100 may cause clinical illness[2] and 2000 may cause death in young cattle. There is a loss of whole blood and hypoproteinemic edema may result. Some irritation to the intestinal mucosa is inevitable and mild or intermittent diarrhea follows. Penetration of the skin by larvae may cause signs of irritation and lead to the introduction of pathogenic bacteria.

27.2.11.6

CLINICAL FINDINGS

In mild infestations in stabled cattle, fidgeting, stamping, and licking of the feet may be observed. Constipation, accompanied by mild abdominal pain is seen in the early stages and is followed by bouts of diarrhea. The cattle are unthrifty and anemic. In severe infestations there is obvious pallor of mucosae, weakness, anasarca under the jaw and along the belly, prostration and death in 2–3 d. The signs in sheep are similar to those in cattle. The convalescent period, even after treatment, is prolonged unless the diet is supplemented to stimulate erythrocyte production.

27.2.11.7

CLINICAL PATHOLOGY

The eggs in feces are similar in appearance to many other gastrointestinal nematodes. Hookworm egg counts of 400–500 epg are usually associated with fatal infestations. As both larvae and adult worms are avid bloodsuckers, clinical signs are often evident before

eggs appear in the feces. The degree of anemia and the presence of occult blood in the feces can be used as a measure of the severity of the infestation.

27.2.11.8 NECROPSY FINDINGS

Hookworms attached to the mucosa are easily found but they may be few in number. In calves, total worm counts of 100 or more suggest a significant level of infestation; counts of over 2000 worms indicate a degree of infestation likely to be fatal. In sheep and goats, 24 adult *G. pachyscelis* have been reported to be fatal, but the usual fatal figure is probably closer to 100. Most of the worms are found in the first few feet of the small intestine and the intestinal contents nearby are often deeply bloodstained. Hookworms often form part of a mixed infection comprising several or many gastrointestinal nematodes.

27.2.11.9 DIAGNOSTIC CONFIRMATION

Anemia, diarrhea, and anasarca are signs common to several diseases and so necropsy is the only certain method of diagnosis.

27.2.11.9.1 DIFFERENTIAL DIAGNOSIS

- Hepatic fasciolosis
- Hemonchosis
- Coccidiosis
- Mycoplasma ovis
- Dietary deficiency of cobalt or copper and chronic molybdenosis.

27.2.11.10 TREATMENT

Most newer broad-spectrum anthelmintics including the benzimidazoles, avermectin/milbemycins, levamisole, and morantel are effective against adult *Bunostomum* spp. in sheep and cattle, but not all products have label claims against larval stages. Moxidectin by injection gives 4 weeks residual protection in sheep against *Gaigeria*. Nitroxynil and rafoxanide, which bind to blood protein and are ingested by bloodsucking worms, are effective. Doramectin has a label claim for *G. pachyscelis* and moxidectin has been shown to protect sheep from reinfection for at least 35 d.[3]

Supportive treatment is essential in this disease because of the severe anemia which occurs. The provision of a mineral mixture containing iron, copper and cobalt is recommended and a general improvement in the quality of the diet, particularly in respect of protein, may shorten the convalescent period.

27.2.11.11 CONTROL

Preventive programs to protect against *Haemonchus* or *Ostertagia* infections will usually give adequate protection against hookworms. Wet surroundings – in pastures, in yards and in barns – should be avoided to reduce the chances of percutaneous infestation and reduce the viability of the free-living larvae. Pens should be cleaned frequently and ample bedding provided. Heavy stocking of sheep or calves in small pens should be avoided. Under conditions of heavy risk, periodic treatment should be administered. The hookworm of cattle will not infect sheep and vice versa, and so alternate grazing may be advantageous although it has been suggested that some species of deer may act as a source of infection for *B. phlebotomum*.

27.2.12 Oesophagostomosis (nodule worm disease) in ruminants and pigs

27.2.12.1 Synopsis

27.2.12.1.1 Etiology

Nematodes of the genus *Oesophagostomum*.

27.2.12.1.2 Epidemiology

In sheep, disease mostly confined to warmer summer rainfall regions; pigs of all ages are susceptible but overt disease uncommon, except in undernourished sows.

27.2.12.1.3

Signs

In sheep, failure to thrive, soft droppings, diarrhea and abdominal pain in severe cases; in sows, weight loss during lactation.

27.2.12.1.4

Clinical pathology

No specific laboratory findings.

27.2.12.1.5

Lesions

Nodules in the wall of intestine.

27.2.12.1.6

Diagnostic confirmation

Necropsy is most reliable; otherwise need to incubate feces and identify infective larvae.

27.2.12.1.7

Treatment

Sheep: all modern broad-spectrum wormers listed for parasitic gastroenteritis; *Pigs*: all wormers listed for stomach worms; not all compounds are active against mucosal larvae.

27.2.12.1.8

Control

General preventive programs for parasitic gastroenteritis are also effective against *Oesophagostomum*. In sows, ensure adequate nutrition.

27.2.12.2

ETIOLOGY

All farm animals except horses can harbor nematodes of the genus *Oesophagostomum*, causing a condition known as ‘nodule worm disease' or ‘pimply gut'. The important species are:

- **Sheep and goats:** *O. columbianum*, *O. venulosum*, and *O. asperum*
- **Cattle:** *O. radiatum* and *O. venulosum*
- **Pig:** *O. dentatum* and *O. quadrispinulatum*.

Oesophagostomum spp. are generally host specific but *O. venulosum* is found in both sheep and cattle. *O. columbianum* can develop in cattle to the point of penetrating the mucosa and producing lesions similar to those in lambs, but without any apparent effect on health.

27.2.12.3

LIFECYCLE

In appearance, *Oesophagostomum* species are stout, white roundworms, the largest growing to 2.5 cm in length. The lifecycle is direct. Eggs passed in the feces hatch and, after undergoing two molts, become infective third-stage larvae. Infestation is thought to occur only by ingestion, but skin penetration has been demonstrated experimentally. The larvae invade the intestinal wall at any level, provoking a nodular host reaction, and some may undergo hypobiosis. They return to the lumen as fourth-stage larvae and egg laying in most species commences in about 40–50 d.

27.2.12.4

EPIDEMIOLOGY

O. columbianum eggs and larvae are particularly susceptible to cold and dryness, but under optimum conditions can reach the infective stage in 6–7 d. Prevalence is therefore highest in warmer temperate or subtropical climates with summer rainfall. If sufficient larvae are ingested, acute disease may occur during the summer months. Lighter infestations or exposure of older animals to infection may give rise to a chronic condition that presents clinically in the following winter when animals are on a low plane of nutrition. Disease in cattle is similarly most common in warmer summer rainfall areas. Nevertheless, the more chronic form of the disease is quite common in ruminants in eastern Canada and the New England states of the United States.

In pigs, *Oesophagostomum* infections are cosmopolitan. The female worms produce large numbers of eggs and in pig houses only the highest standards of hygiene will prevent infections from persisting. Outdoors, the larvae thrive best when sheltered by thick vegetation. Numbers decline markedly during dry summers on bare soil or during the winter.[1] Some larvae, however, can overwinter even in Scandinavia, but cold Canadian winters kill all free-living stages.[2] A periparturient rise in fecal egg counts has been described in sows but it is not as constant a feature as the similar phenomenon in ewes. The periparturient egg-rise (PPER) is closely related to lactation and terminates when the piglets are weaned. When it occurs, it can be an important source of contamination in the farrowing house.[3] *Oesophagostomum* has been associated with the thin sow syndrome, in

which sows rapidly lose condition late in pregnancy and while they are lactating. Fecal egg counts may be very high but parasitism is only a contributory factor. The primary cause is inadequate nutrition. In group-fed animals, timid sows not able to secure an adequate share of the ration satisfy their hunger by eating bedding, thereby increasing their intake of infective larvae.

27.2.12.5

PATHOGENESIS

The size of the nodules in the intestinal wall, and hence their pathogenicity and economic importance to the meat industry, varies with the worm species and immunity of the host. In ruminants, for example, *O. columbianum* provokes a massive host response while *O. venulosum* does not produce visible lesions. In pigs, *O. quadrispinulatum* nodules are larger than those of *O. dentatum*.

O. columbianum larvae in young sheep exposed for the first time stay in the wall of the anterior small intestine for about 5 d. Some subsequently enter the mucosa a second time in the large intestine, while others develop directly to adults. In second and subsequent infections, few larvae develop directly to adults and most are arrested in either the first or second mucosal phases.[4] Persistence of larvae in the intestinal wall for long periods is thought to indicate host immunity, thus in older sheep, nodules develop in the intestinal wall at any level and may occasionally be present in nearby organs. Larvae may remain alive in these nodules for periods of up to 1 year but many are destroyed by the host response. When the resistance of the animal is lowered, due for example to poor nutrition, 1553
larvae leave the nodules, re-enter the intestinal lumen and pass down to the colon to 1554
become adults. This is the probable explanation for three common findings at necropsy:

1. Young sheep with many adult worms and no nodules
2. Adult sheep with many nodules and no adult worms
3. Adults with both.

Oesophagostomosis is sometimes implicated as a primary cause of intussusception in young sheep.

Young susceptible ruminants generally suffer as a result of the emergence of larvae from the mucosa, which provokes a catarrhal colitis, and the feeding activities of the adults, which produce small ulcers and some mucosal bleeding.[5] In older, immune animals the nodular reaction plays a more important role. *O. radiatum* and *O. columbianum* cause:

- Anorexia
- Severe and persistent mucoid diarrhea
- Loss of weight
- Anemia
- Hypoproteinemia
- Death.

The hypoproteinemia follows edema of the cecum and colon and is caused by loss of albumin into the lumen.[6] Anemia results from blood loss when mucosal larvae re-enter the lumen. The fall in plasma fibrinogen levels and platelet numbers observed 6–7 d after primary infection of calves probably aggravates this loss.[7] Nodules eventually caseate and calcify and may cause interference with intestinal motility or local peritonitis and adhesion formation, which leads to intussusception or stenosis. In sheep the nodules can cause considerable pain and result in an arched back (‘humpy back') and a stilted gait. The nodules in pigs are much smaller, although edema and thickening of the colon and cecum can develop in the case of heavy infestation. Outbreaks of necrotic enteritis may be activated in pigs carrying *Salmonella* spp. populations.[8]

27.2.12.6

CLINICAL FINDINGS

In heavily infested sheep, severe persistent diarrhea may occur in young animals. More commonly, older sheep in the winter months will show an intermittent passage of semi-soft droppings which contain excessive amounts of mucus and occasionally blood. There is rapid loss of condition, hollowing of the back, stiffness of gait and elevation of the tail. Nodules may be palpated on rectal examination. Anemia is not characteristic and is never marked.

Young calves may show anorexia, diarrhea, emaciation, and anemia. Initially the diarrhea may alternate with constipation, but later it is continuous and is dark and fetid.

In pigs, clinical signs are less severe. Loss of condition and diarrhea in weaners and growers have been attributed to heavy infection, but deleterious effects, if any, are normally found at a subclinical level. In the ‘thin sow' syndrome, lactating sows become

thin or in severe cases emaciated, even though they have a good appetite but there is usually no diarrhea.

27.2.12.7

CLINICAL PATHOLOGY

There are no specific laboratory tests The eggs in feces are similar in appearance to those of many other gastrointestinal nematodes. Also, the severity of the disease may bear no relation to the number of eggs in the feces; counts vary widely with the season and the stage of development of the disease. In the early stages of a massive infestation, signs may be evident but there may be no eggs in the droppings. After the prepatent period in young sheep, eggs are usually present in large numbers and may be accompanied by living adult worms. In chronic cases however, very few eggs may be passed. Serum albumin concentrations are low in severe cases and anemia may be detected in cattle.

27.2.12.8

NECROPSY FINDINGS

In early acute cases there is a mild catarrhal enteritis and larvae may be detectable in scrapings of intestinal mucosa. In the later more chronic stage, adult worms are easily visible in the colon. They are usually lying in thick mucus overlying a chronic catarrhal colitis. *O. columbianum* is very pathogenic and 200 adult females is considered a heavy infestation. Nodules, when they are present, may be found at all levels of the intestine; they measure up to 6 mm in diameter and, depending on their age, contain green, pasty or yellow-brown, crumbly, partly calcified material. There may be a great deal of thickening of the intestinal wall and local peritonitis.

27.2.12.9

DIAGNOSTIC CONFIRMATION

A definite diagnosis of oesophagostomosis can only be made by necropsy examination or identification of larvae from a fecal culture.

27.2.12.9.1

DIFFERENTIAL DIAGNOSIS

- Trichostrongylosis in sheep is also at its peak during the winter but diarrhea is more evident
- Hyostrongylosis also causes emaciation in lactating sows but is confined to outdoor herds
- Malnutrition, especially when sheep are housed and poorly fed.

27.2.12.10

TREATMENT

All modern broad-spectrum compounds are effective against adult *Oesophagostomum*. Moxidectin provides up to 4 weeks' protection from reinfection with *O. columbianum* in sheep. *Oesophagostomum* spp. strains resistant to pyrantel have been detected on some pig farms in Denmark.[9]

27.2.12.11

CONTROL

In sheep and cattle, the principles of control described under parasitic gastroenteritis in ruminants apply also to *Oesophagostomum* infections.

In pigs, the thin sow syndrome is unlikely to be cured or prevented by anthelmintic treatments alone; due consideration must also be given to the nutritional requirements of the animals at risk. To prevent contamination of the farrowing house, sows should be treated before entry. Pigs should be treated at weaning and each time they are moved on to new accommodation. Boars should be treated at least once a year.[10] Alternatively, it may be more convenient to treat all pigs on a premises simultaneously with a medicated feed. The dosing interval should be determined by fecal egg-counts performed on a representative sample of all age groups in the herd. Overdependence on anthelmintic therapy should be avoided as resistance can develop in *Oesophagostomum* populations.[9] The demonstration that diets containing highly degradable and rapidly fermentable carbohydrates can considerably reduce *O. dentatum* burdens and fecal egg-counts[11] indicates the possibility of an alternative approach to control.

In grazing pigs, the ability of the eggs and larvae to survive on the pasture must be considered. In the United Kingdom, eggs deposited in the winter and early spring do not reach the infective stage but infective larvae can survive for a year in feces or on pasture Under these conditions treatment of pigs in the autumn with a move to clean pasture will reduce pasture contamination through the following spring and early summer.[12] An additional treatment in spring may give additional security.

27.2.13 Parasitic gastritis in pigs

27.2.13.1 Synopsis

27.2.13.1.1 Etiology

The nematodes *Hyostrongylus rubidus*, *Ascarops*, and *Physocephalus*.

27.2.13.1.2 Epidemiology

Infections occur in outdoor husbandry systems; *Hyostrongylus rubidus* has a direct lifecycle, but *Ascarops* and *Physocephalus* use dung beetles as intermediate hosts.

27.2.13.1.3 Signs

Generally asymptomatic but heavy infections can produce gastritis; sows with *H. rubidus* may become thin during lactation.

27.2.13.1.4 Clinical pathology

Eggs of *Ascarops* and *Physocephalus* in feces are characteristic; those of *H. rubidus* are similar to *Oesophagostomum*.

27.2.13.1.5 Lesions

Excess mucus; gastritis; often ulceration of glandular part of stomach; nodular hyperplasia in hyostrongylosis.

27.2.13.1.6 Diagnostic confirmation

Demonstration of eggs of *Ascarops* or *Physocephalus*; examination of larvae from fecal culture for *H. rubidus*.

27.2.13.1.7 Treatment

H. rubidus: doramectin, ivermectin, fenbendazole, flubendazole, febantel, oxibendazole, thiophanate, levamisole, and dichlorvos; *Ascarops*: ivermectin.

27.2.13.1.8 Control

Good husbandry practices, such as rotating pastures, normally suffice.

27.2.13.2 ETIOLOGY

Three categories of nematode inhabit the stomach of the pig. The first is a trichostrongylid, *Hyostrongylus rubidus*. This is closely related to the *Ostertagia* spp. of ruminants and occurs in most countries where pigs are kept. The next group comprises members of several related genera including *Ascarops strongylina*,*A. dentata*, and *Physocephalus sexalatus*, which occur in the United States, Southeast Asia, and Australia, and *Simondsia paradoxa*, found in parts of Europe and India. Finally, *Ollulanus tricuspis* is a very small nematode (0.7–1.0 mm) that causes gastritis on rare occasions in pigs, cats, foxes, and dogs.

27.2.13.3 LIFECYCLES

H. rubidus is a small (0.5–1.25 cm) thin, red worm which has a lifecycle very similar to that of *O. ostertagi*. Eggs develop at temperatures between 10 and 27°C (50 and 80°F). In

the United Kingdom, eggs deposited outdoors from May to October develop into infective larvae. These larvae survive on pasture for up to 10 months but are rapidly killed by desiccation and by freezing. Transmission occurs by ingestion of the infective larvae, which spend the next 13–14 d in the gastric glands. They then return to the lumen and the first eggs are passed 20–25 d after infection. In some circumstances larvae become hypobiotic and remain in the gastric mucosa for several months.

Ascarops and *Physocephalus* are thick, white worms 1–2.5 cm long. They have indirect lifecycles; eggs passed in the feces of the pig are eaten by dung beetles, in which hatching and development to infective larvae occur. Infestation of the final host occurs when pigs eat infested beetles. Little is known of the biology of *Simondsia paradoxa*.

27.2.13.4

EPIDEMIOLOGY

The stomach worms of pigs are almost exclusively confined to outdoor management systems. The reason for this is different in each group. With *Ascarops* and *Physocephalus*, it is a consequence of the essential role of the dung-beetle in the lifecycle. In the case of *H. rubidus*, it is because the daily output of eggs by each female is so sparse that the lifecycle is unlikely to persist in pig houses practising a reasonable standard of hygiene. Young pigs are the most susceptible to hyostrongylosis but adult sows, especially when lactating, may also be affected. Hypobiosis is seasonal but disease outbreaks analogous to Type II ostertagiosis have not been reported.

27.2.13.5

PATHOGENESIS

Developing *H. rubidus* provoke hyperplastic nodular lesions in the glandular part of the stomach. These and consequent biochemical and physiological sequelae are similar to those described for *O. ostertagi*. *Ascarops* and *Physocephalus* lie close to the gastric mucosa where they stimulate excessive mucus production. Heavy infections cause a catarrhal gastritis.

27.2.13.6

CLINICAL FINDINGS

The effect of *H. rubidus* on young pigs is not usually clinically apparent.[1] Heavy infestations may be associated with anemia, unthriftiness, poor growth and diarrhea.[2] Signs in adult sows are usually seen during lactation. Affected animals lose more weight than normal and are slow to regain condition after weaning. In severe cases, sows may become emaciated. There may be pallor due to anemia and often a depraved appetite, but no

diarrhea. Adult sows often carry heavy infestations without clinical illness but sudden death due to hemorrhage from gastric ulcers or to peritonitis by ulcerative perforation has been observed on rare occasions.[3] Although *Ascarops* and *Physocephalus* are common in many areas, most infections are low grade and without clinical effect. Heavy infections can lead to inappetence and other signs of gastritis.

27.2.13.7

CLINICAL PATHOLOGY

Fecal examination is not very useful for the diagnosis of hyostrongylosis as the eggs of *H. rubidus* are indistinguishable from those of the less pathogenic but more prolific *Oesophagostomum* spp. *Physocephalus* and *Ascarops* spp. eggs are small, thick-shelled and contain a larva when laid.

27.2.13.8

NECROPSY FINDINGS

The presence of *H. rubidus* is easily missed as the worms are slender and often lie beneath a thick layer of mucus. The gastric mucosa is hyperemic and nodular lesions are present. There may be one or more deep ulcers in the glandular region of the stomach. These may contain clusters of adult *H. rubidus*. In severe cases the mucosa is thickened and edematous, and covered with a diphtheritic pseudomembrane. In *Physocephalus* and *Ascarops* infections, adult worms are readily visible lying in mucus on the gastric mucosa. There is an obvious gastritis in heavy infections and ulceration may occur.

27.2.13.9

DIAGNOSTIC CONFIRMATION

Confirmation of infection with *H. rubidus* is made by examination of larvae from fecal cultures. Those of *H. rubidus* are longer and more vigorously motile than those of *Oesophagostomum* spp. As *H. rubidus* produces so few eggs, even small numbers of larvae may indicate a pathogenic worm burden. Elevated serum pepsinogen concentrations may also be indicative of infection.[4]

27.2.13.9.1

DIFFERENTIAL DIAGNOSIS

H. rubidus must be differentiated from other causes of unthriftiness or emaciation such as:

- Swine dysentery
- Necrotic enteritis

- Coccidiosis
- Infestation with *Oesophagostomum* spp.
- Thin sow syndrome
- Malnutrition

27.2.13.10 TREATMENT

Doramectin (0.3 mg/kg by injection), ivermectin (0.3 mg/kg by injection or 0.1 mg/kg/d for 7 d in feed), fenbendazole (5 mg/kg in feed as a single dose or divided over 7–14 d) and flubendazole (5 mg/kg as a single dose or 30 g/t finished feed given for 5–10 d) are active against fourth-stage and adult *H. rubidus*. Additionally, febantel (5 mg/kg), oxibendazole (15 mg/kg or 1.6 mg/kg/d for 10 d) and thiophanate have label claims only for the adult worm. Levamisole and dichlorvos have also been widely used in the treatment of pig nematodes. In-feed ivermectin is also effective against *A. strongylina*.

1555 1556

27.2.13.11 CONTROL

Standard hygienic precautions including frequent removal of manure, the provision of drainage in outside pens and rotation of pastures will reduce environmental contamination. Control of the dung beetle intermediate hosts of *Physocephalus* and *Ascarops* is impracticable.

Hyostrongylosis is most likely to affect sows during lactation and so animals at risk should be dosed before farrowing.[5] The behavior of *H. rubidus* larvae on pasture is similar to that described for *Oesophagostomum* and control schemes should be effective for both parasites.[6]

27.2.14 ## Ascarid infections in pigs, horses and cattle

27.2.14.1 ### Synopsis

27.2.14.1.1 #### Etiology

Nematode worms from the ascarid family: *Ascaris suum* in pigs, *Parascaris equorum* in horses and *Toxocara vitulorum* in buffalo and cattle.

27.2.14.1.2 #### Epidemiology

Transmission is by ingestion of highly resistant and long-lived larvated eggs; *T. vitulorum* is also transferred via colostrum.

27.2.14.1.3 #### Signs

Heavy infestation leads to poor growth and afebrile diarrhea, sometimes with obstructive jaundice, intestinal obstruction and respiratory signs.

27.2.14.1.4 #### Clinical pathology

Characteristic eggs in feces and a marked eosinophilia.

27.2.14.1.5 #### Lesions

Petechial hemorrhages in lungs and fibrotic spots on the liver.

27.2.14.1.6 #### Diagnostic confirmation

Demonstration of characteristic eggs in feces.

27.2.14.1.7

Treatment

Pigs: ivermectin, doramectin, flubendazole, febantel, oxibendazole, thiophanate, pyrantel tartrate, and levamisole. *Horses*: ivermectin, moxidectin, febantel, fenbendazole, mebendazole, oxibendazole, and pyrantel embonate.

27.2.14.1.8

Control

Pigs, *horses*: Keep young stock away from sites where eggs may accumulate. *Cattle/buffalo*: prophylactic anthelmintic treatment of 10–16 day old calves.

27.2.14.2

ETIOLOGY

Each species has its own ascarid: *Ascaris suum* in pigs and *Parascaris equorum* in horses are cosmopolitan, while *Toxocara vitulorum* is an important cause of mortality in buffalo calves in India and Southeast Asia. Genetic studies show that although *A. suum* of the pig is very similar to *A. lumbricoides* of man, host-specific differences do exist[1] and cross-infections occur only infrequently.[2,3] There is no ascarid specific for sheep but they may rarely become infected with *A. suum*.

27.2.14.3

LIFECYCLE

A. suum and *P. equorum* have similar lifecycles. The adult worms are long (20–50 cm), cylindrical, pointed at both ends and have a thick, glistening, yellow-white cuticle. They live in the small intestine and lay very large numbers of thick-shelled eggs. These are not infective until a larva has developed inside. This process needs suitable warmth and humidity and takes place over a period of several weeks. When swallowed, infective eggs hatch quickly in the intestine of the host and the larvae migrate through the intestinal wall, reach the portal vein and are transported to the liver. They cross to the hepatic venous system and travel to the lungs, are passed up the bronchi and trachea to the pharynx, are swallowed and come to rest in the intestine where they mature. The prepatent period (time from infestation to the appearance of eggs in the feces) is 6–8 weeks for *A. suum* and 11–15 weeks for *P. equorum*.[4]

Toxocara vitulorum has a more complex lifecycle. When eggs are ingested by cattle or buffalo more than 4–5 months of age, the larvae instead of traveling to the intestine settle in somatic tissues without developing or growing. Subsequently they become activated

around calving and migrate to the udder. They transfer to the calf in the colostrum and grow to the adult stage in the intestine.

27.2.14.4

EPIDEMIOLOGY

In pigs and horses the only route of infection is by ingestion of larvated eggs. Because the eggs have very thick walls the infective stage is protected from deleterious environmental influences. Few disinfectants will harm them and they are very resistant to cold but survive most readily in cool, moist surroundings. Periods of survival of up to 5 years have been recorded. In the United Kingdom, *A. suum* eggs shed from September to May become infective more or less synchronously in July and the number of eggs becoming infective then falls away rapidly. This coincides with the prevalence of damaged livers recorded at bacon factories.[5] Transmission is therefore seasonal but as ascarid eggs are very resistant and can overwinter, pigs and horses may in the absence of good hygiene become infected at all periods of the year.[6] Clinical ascariosis is usually associated with conditions that allow infective eggs to accumulate. This may happen where, for example, the stocking rate is high and the same paddocks are used year after year,[7] or when indoor pens are inadequately cleaned.

Protective immunity develops and consequently only the young are seriously affected. Under field conditions, eggs are passed by foals from 12–13 weeks of age and spontaneous expulsion of worms occurs 6–9 weeks later. Eggs are seen occasionally in the feces of very young foals but this is thought to be due to the ingestion of uninfective eggs during coprophagia. In older animals no clinical signs are observed but infested animals, particularly adult sows and yearling horses, continue to contaminate their surroundings and are an important link in the chain of infection.

T. vitulorum larvae are present in greatest numbers in the colostrum 2–5 d after calving and few are present after day 9.[8] Mature worms are present in the intestine of the calf by 10 d of age and eggs are passed by 3 weeks. Worms are expelled by 5 months of age, thus toxocarosis is a calfhood disease.

27.2.14.5

PATHOGENESIS

Migration of larvae through the liver results in hemorrhage and fibrosis, the latter appearing as white spots under the capsule. In heavy infection diffuse fibrosis may occur. The most serious damage occurs in the lungs where the larvae provoke alveolar injury with

edema and consolidation. This damage can exacerbate pre-existing lung infections or provide a portal of entry into the body for pyogenic organisms. Immunity to migrating larvae is acquired and can be transferred through colostrum or immune serum.

In animals other than pigs, *A. suum* larvae migrate and develop but the worms do not normally reach the small intestine. During this process severe clinical signs of pulmonary involvement may appear. The disease has been produced experimentally in lambs and calves and has also been observed as a field occurrence in yearling cattle.[9–11]

Foals with *P. equorum* have reduced gut motility, an increase in the ratio of body water to body solids and a lowering of the body pool of albumin.[12]

27.2.14.6

CLINICAL FINDINGS

In pigs up to 4–5 months old, clinical signs associated with heavy infestation are poor growth, an afebrile diarrhea and lowered resistance to other disease. There is some evidence that exposure to parasites during the growing phase without anthelmintic treatment causes permanent damage to growth potential.[13] Adult worms may be vomited up and occasional cases of obstructive jaundice and intestinal obstruction or rupture occur. There may be coughing while larvae are passing through the lungs but this is not marked and there is seldom sufficient damage to cause a noticeable increase in respiratory rate or depth. In rare cases the infestation may be so severe that pigs manifest severe dyspnea or die of acute hepatic insufficiency. Enzootic pneumonia of pigs and swine influenza are reported to be much more serious diseases when accompanied by heavy *A. suum* infections, and breaks in hog cholera vaccination with live virus have been attributed to this cause *A. suum* in other host species produces fever, dyspnea, and anorexia about the 8th day after infestation.[9]

1556 1557

Effects in foals and calves due to heavy infestation with *P. equorum* and *T. vitulorum* are similar to those observed in young pigs and include poor coat, diarrhea, and occasionally colic. In addition, in foals, convulsions, intestinal obstruction, and perforation may occur. Lung damage may give rise to fever, coughing and a mucopurulent nasal discharge. In calves, anemia and steatorrhea are additional signs.

27.2.14.7

CLINICAL PATHOLOGY

Characteristic eggs are usually present in large numbers in the feces of clinically affected animals. A marked eosinophilia often accompanies the early stages of infestation in pigs and in other species and has been shown to persist in calves for at least 1 year.

27.2.14.8

NECROPSY FINDINGS

In the early stages of a massive infestation, there are subpleural hemorrhages, and edema and congestion of the lungs. The pleural cavity may contain blood-stained fluid. The liver is enlarged and congested and there may be hemorrhages under the capsule. Microscopically, necrotic tracts and sections of larvae are observed. In species other than the pig, infestation with *A. suum* is accompanied by emphysema, alveolar wall thickening with fibrin, eosinophils and hemorrhage in the lungs, and necrotic tracts in the liver.

In chronic cases the capsule of the liver is marked with white spots of small diameter which may, in severe cases, be confluent and constitute a network of connective tissue. Histologically, the necrotic tracts have been replaced by fibrous tissue. The carcass is usually in poor condition and may be jaundiced. Large numbers of mature worms may almost fill the lumen of the small intestine.

27.2.14.9

DIAGNOSTIC CONFIRMATION

Ascarid eggs are brown and have thick walls with a pitted surface. Fecal egg counts in excess of 1000 epg are considered to be indicative of significant infection. Migrating larvae are too small to be observed by the naked eye at postmortem examination. They can be recovered from macerated lung tissue by the Baermann technique or seen microscopically in scrapings of bronchial mucus.

27.2.14.9.1

DIFFERENTIAL DIAGNOSIS

Early stages of massive infection:

- Enzootic pneumonia in pigs
- Chronic form of *Rhodococcus equi* pneumonia in young foals
- Other forms of pneumonia in calves.

Chronic infection:

- Other causes of unthriftiness including malnutrition and chronic enteritis due to infections with *Salmonella* and *Brachyspina* spp.

27.2.14.10 TREATMENT

27.2.14.10.1 Pigs

In pigs, ivermectin or doramectin at 0.3 mg/kg and flubendazole 5 mg/kg are effective against adult and fourth-stage (intestinal) larvae of *A. suum* while fenbendazole 5 mg/kg, febantel 5 mg/kg, oxibendazole 15 mg/kg, thiophanate, pyrantel tartrate, and levamisole are effective against the adult worm. Ivermectin, fenbendazole, flubendazole, thiophanate, and pyrantel may be given in feed as divided doses over several days. Ivermectin may have some activity against migrating larvae.[14]

27.2.14.10.2 Horses

In horses, ivermectin 0.2 mg/kg, moxidectin 0.4 mg/kg, febantel 6 mg/kg, fenbendazole 7.5 mg/kg, mebendazole 5–10 mg/kg, oxibendazole 10 mg/kg, and pyrantel embonate 19 mg/kg are all effective against adult *P. equorum*. Ivermectin, moxidectin, and fenbendazole are also active against immature forms in the intestine.

27.2.14.10.3 Buffalo calves

In buffalo calves, the limited data available suggest that pyrantel has good efficacy against both immature and adult worms. A dose of 250 mg for a calf has given good results.[8] Other compounds such as levamisole, febantel, oxfendazole, and even piperazine can be used for treatment but may not expel all worms.

27.2.14.11 CONTROL

Important lifecycle features which must be taken into account when devising a control program for ascarid infections are:

- The worms are prolific egg layers
- The infective eggs are very resistant and long lived

- Young animals are most susceptible.

Emphasis must be placed on preventing the environment from becoming contaminated. This is achieved by periodic treatment of the animals likely to be shedding eggs – asymptomatic adult carriers as well as the more vulnerable young stock. Exposure of young pigs and foals to contaminated soil or bedding should be avoided.

Unnecessary treatments can be avoided by regular monitoring with fecal egg counts. In intensive pig-raising systems on concrete floors, the risk of ascarid infestation can be greatly reduced, but rarely eliminated, with good standards of hygiene. In the case of straw yards, epidemiological studies in the United Kingdom[5] suggest that all bedding should be removed at the end of June (to remove eggs shed in preceding months before they become infective) and again at the end of August (to remove eggs deposited in the summer). If pigs are allowed access to small earthen yards, these must be kept well drained and the manure removed frequently. Control is difficult in free-range systems as the eggs become infective in 4–6 weeks in summer and many persist over the winter.[15] Deep ploughing of contaminated soil after use will reduce risk of *A. suum* and *Trichuris suis* eggs infecting future batches of pigs.

If farrowing pens are regularly cleaned with high-pressure water and sows are treated immediately prior to entry, it may be possible to control infection in piglets without anthelmintic treatment. Breakdowns may occur as ascarid eggs are adhesive and not all will be washed away by hosing. For the same reason, eggs are easily introduced from outside on boots etc. It may therefore be necessary to treat piglets at weaning. Ascarids may be controlled in growing pigs by periodic anthelmintic treatments, but this has to be combined with rigorous hygiene to eliminate liver damage caused by migrating larvae.

Young foals present more of a problem as they often run on permanent pasture used by foals in previous years. Such pastures may become heavily contaminated with eggs. Recommendations for control include[16]:

- Thorough cleaning and disinfection of the maternity stall after each foaling
- Use of small exercise paddocks which should preferably have been rested from occupation by horses for a year
- Weekly removal of manure from the pasture. The foals should be routinely treated at about 10–12 weeks of age when the worms are first becoming mature and again at

bimonthly intervals. In this way heavy egg contamination of the pasture can be avoided.

Early signs of the possible development of anthelmintic resistance in *P. equorum* are starting to appear.[17]

In buffalo calves, a single anthelmintic treatment at 10–16 d of age using a compound with high activity against larval stages gives good control of *T. vitulorum*.

27.2.15 ## Strongylosis (redworm infestation) in horses

27.2.15.1 ### Synopsis

27.2.15.1.1 #### Etiology

Two nematode subfamilies: the Strongylinae (large strongyles) and Cyathostominae (known variously as small strongyles, small redworms, trichonemes, cyathostomes, or cyathostomins).

27.2.15.1.2 #### Epidemiology

Eggs are shed by horses of all ages; the lifecycle is direct; infective larvae develop seasonally on pasture; hypobiotic cyathostomin larvae can cause severe disease when they resume development in late winter.

27.2.15.1.3 #### Signs

General strongylosis: ill-thrift, weight loss, poor hair coat, and impaired performance. Verminous arteritis (associated with *Strongylus vulgaris*): variable, including colic and diarrhea. Larval cyathostominosis: rapid weight loss, often with sudden onset diarrhea.

27.2.15.1.4 #### Clinical pathology

Strongylid eggs in feces (except disease caused by larvae); reduced hemoglobin, erythrocyte counts and packed cell volumes; leukocytosis; eosinophilia (with migrating larvae); hyperglobulinemia, particularly IgG(T); hypoalbuminemia.

27.2.15.1.5 #### Lesions

General strongylosis: large numbers of adult worms in cecum and colon; hemorrhagic inflammation of mucosa with multiple small ulcers, large and small nodules. *Larval cyathostominosis*: mucosa grossly inflamed with large numbers of larvae appearing as brown specks. Verminous arteritis: wall of cranial mesenteric artery greatly thickened, organizing thrombi and larvae on internal surface; ischemia or necrosis of parts of

intestinal wall due to emboli. *Migratory larvae*: seen in various subserosal sites; some cause nodules in the liver.

27.2.15.1.6 Diagnostic confirmation

Few pathognomonic indicators; judgment made on overall appraisal of clinical history, presenting signs and laboratory findings; arteritis of cranial mesenteric artery sometimes palpable *per rectum*; immature worms sometimes in feces in larval cyathostominosis.

27.2.15.1.7 Treatment

General strongylosis: ivermectin, moxidectin; benzimidazoles, e.g. febantel, fenbendazole, mebendazole, oxibendazole; pyrantel. *Migrating strongyles*: ivermectin, moxidectin; fenbendazole (special dose). *Larval cyathostominosis*: fenbendazole (special dose), moxidectin.

27.2.15.1.8 Control

Twice-weekly removal of feces from pastures; mixed or alternate grazing; routine dosing to prevent contamination of pasture with eggs. *Larval cyathostominosis*: 5-day preventive fenbendazole treatment in early winter.

27.2.15.2 ETIOLOGY

The redworms (strongyles) are nematodes commonly found in the large intestine of horses and other Equidae. They belong to two subfamilies: the Strongylinae (large stronglyes) and Cyathostominae (known variously as small strongyles, small redworms, trichonemes, cyathostomes or cyathostomins). The large strongyles include *Strongylus vulgaris*, *S. edentatus*, and *S. equinus*, which migrate extensively through the body, and *Triodontophorus* spp. and *Oesophagodontus robustus*, which do not. The cyathostomins comprise more than 40 non-migratory species belonging to genera including *Cylicostephanus*, *Cyathostomum*, *Cylicocyclus*, *Cylicodontophorus*, *Poteriostomum*, *Gyalocephalus*, and *Cylindropharynx*.[1] Of these, about 10 species occur commonly.

27.2.15.3 LIFECYCLE

Eggs are passed in the feces and under suitable climatic conditions produce infective third-stage larvae from 7 days onwards. As in many other parasitic conditions, the survival of eggs and larvae is favored by shade, moisture and moderate temperature. Desiccation is

particularly detrimental to their development. Some eggs and larvae may withstand freezing temperatures but development ceases below 7.5°C (46°F) to be resumed when temperatures increase. Optimum chances for infection of the host occur in the early morning or evening, when dew produces a moisture film on plants, or after rain, both of which give conditions that encourage larvae to migrate onto pasture. The lifecycle of all species is direct; horses become infected by ingestion of the infective larvae.

After ingestion, the larvae of non-migratory strongyles, such as the cyathostomins, exsheath and enter the walls of the cecum and colon, where they remain in small subserous nodules for 7–18 weeks before breaking out into the lumen of the intestine. The time spent in the mucosa depends on:

- The species
- The season of the year
- The age and degree of immunity of the host.

They can become arrested in their mucosal development and their synchronous emergence some weeks later may provoke severe clinical signs. This may occur spontaneously, particularly in late winter, or may be induced by anthelmintic treatment. Expulsion of the adult worm population seems to remove an inhibitory feed-back mechanism and may provoke clinical signs.[2] Hypobiotic early third stage larvae are present in the mucosa at all seasons of the year.[3]

Larvae of *S. edentatus* penetrate the intestine and travel via the portal vessels to the liver, where larvae remain and produce hemorrhagic tracts for a month or so. They then migrate via the hepatorenal ligament to the connective tissue under the peritoneum and form hemorrhagic nodules. After about 3 months, they return via the root of the mesentery to the large bowel wall and again form hemorrhagic nodules, which finally rupture and release the worms into the lumen. Adult egg-laying females are present from 40 weeks.[4] Larvae may be found in other organs, e.g. the testes, but these larvae do not return to the intestine. *S. equinus* migrates via the liver to the pancreas and peritoneal cavity but how they return to the intestine is uncertain.

Larvae of *S. vulgaris* penetrate the intestinal wall, molt to the fourth larval stage in the submucosa and then pass into and up small arteries. By day 14, they have reached the cranial mesenteric artery, where they develop to late fourth-stage larvae. In 3–4 months they molt and the young adults then return to the intestine via the lumina of the arteries.

1558

1559

Nodules are formed in the intestine wall and later rupture, releasing adults into the lumen of the intestine. The prepatent period is 6 months.

27.2.15.4

EPIDEMIOLOGY

Strongylosis is a common disease of horses throughout the world and causes deaths when control measures are neglected. In areas with cold winters and mild summers, egg deposition peaks in spring and remains high over summer.[5] At this time, temperatures are suitable for larval development and massive contamination of infective larvae may occur in late summer and early autumn, when young susceptible horses are present. *S. vulgaris* larvae can overwinter in considerable numbers in Europe.[6] If the summers are hot and dry, only a small proportion of strongyle eggs develop to larvae and these may be shortlived, but continual reinfestation keeps pasture contamination high.

In subtropical regions, eggs can hatch throughout the year and larval availability is influenced more by rainfall than temperature. For example, in Florida in the United States, fecal egg counts remain high throughout the year and there is an autumn rise in infective larvae.[7] Such associations between disease risk and local climate have important implications in the timing of treatments.

The onset of disease following ingestion of large numbers of larvae depends on the maturation period of the parasite in the host and whether it is the immature or adult stages that are pathogenic. Outbreaks of disease due to the emergence of small strongyles after hypobiosis are commonly seen in Europe in late-winter and early-spring (winter or larval cyathostominosis),[8,9] while arterial lesions due to larval *S. vulgaris* are first seen in late summer and reach a maximum by midwinter.

Mares are the main source of infection for younger horses[10] as many adults carry appreciable strongyle burdens and pass large numbers of eggs. Nevertheless, horses do gain some acquired immunity to infection and so young stock are the most susceptible.[11] Possibilities for vaccination are being investigated[12] but a commercial product seems an unlikely prospect in the short term.

The extensive use of anthelmintics with high efficacy at regular intervals has resulted in a marked decline in the prevalence of *S. vulgaris* in many regions.[13] The cyathostomins, on the other hand, are becoming increasingly important. This may be due to any of the following factors[14]:

- Insusceptibility of mucosal cyathostomins to many drugs
- Selection for benzimidazole-resistant worms
- Selection for shorter egg reappearance periods.

27.2.15.5

PATHOGENESIS

The disease processes associated with the strongyles can be divided into those produced by migrating larvae, those provoked by the mass emergence of mucosal larvae and those associated with adult worms. Heavy intestinal infection can alter intestinal motility, permeability, and absorption.

The larvae of *S. vulgaris* are the most pathogenic, causing arteritis, thrombosis and thickening of the wall of the cranial mesenteric artery. Emboli may break away and lodge in smaller blood vessels, leading to partial or complete ischemia in part of the intestine, thus producing colic. The result of this depends on the length of the segment of intestine affected and the ability of the collateral blood supply to become established before necrosis and gangrene occur. It is not clear whether the ischemia is due directly to the mechanical effects of embolism or to consequent pathophysiological events.[15] Whatever the cause, greatly enhanced mobility proximal to the lesion follows and can cause volvulus or torsion.[16] Intussusception is seen occasionally. Colic may also be caused by pressure of the thickened cranial mesenteric artery on the mesenteric plexus.

Other arterial lesions associated with migrating *S. vulgaris* larvae include aneurysm of the cranial mesenteric artery but this is a relatively rare occurrence. More often, larvae aberrantly migrating beyond the cranial mesenteric artery cause migratory tracts and thrombi in other blood vessels. Multiple lesions may be seen in the cecal and colic arteries which may completely occlude the lumen and cause gangrene in parts of the bowel. Smaller lesions are occasionally seen in iliac, renal, splenic, hepatic and coronary arteries. Aortic and iliac thrombosis may result in hindlimb lameness.[17] Field and experimental cases of cerebrospinal nematodosis due to *S. vulgaris* invasion of the central nervous system have been reported.[18]

***Strongylus* sp. larvae** returning to the intestine cause large nodules in the wall of the cecum and colon Considerable hemorrhage may follow when these rupture to release the worm into the lumen of the intestine. In very heavy burdens, bleeding sufficient enough to cause death can occur.

Developing cyathostomin larvae provoke the formation of small nodules which may be superficial or submucosal, depending on species. In heavy infections, the emergence of large numbers of larvae over a short period causes inflammation of the cecum or ventral colon, with small ulcers where larvae have emerged, hemorrhages of varying sizes and excess mucus production. Typically, this leads to weight-loss, diarrhea and sometimes a variety of other clinical manifestions including colic and cecocecal intussusception.[19] Affected animals may sometimes secrete *Salmonella*.[9]

Adult strongyles can be divided into those that cause blood losses and those that are superficial tissue feeders. *Strongylus* spp. have large buccal cavities which they use to draw in and digest plugs of mucosa, while secreting anticoagulants to aid the ingestion of blood. Hemorrhage continues from feeding points after worms detach to find a new attachment sites. *Triodontophorus* spp. and *O. robustus* feed similarly but are less harmful as they have smaller buccal capsules. An exception is *T. tenuicollis* as this species attaches in groups in the right dorsal colon and can cause large ulcers. The small strongyles (cyathostomins) have even smaller buccal cavities and produce only superficial damage so that even relatively large numbers (tens or hundreds of thousands) of adults often cause little apparent harm.

27.2.15.6

CLINICAL FINDINGS

In natural infestations it is often impossible to quantify the effects of individual strongyle species as the clinical picture usually represents the combined effects of a mixed infestation. Ill-thrift, poor hair coat, impaired performance, weight loss and anemia are signs associated with a ‘wormy' horse. The greatest losses are probably due to the failure of young horses to grow optimally and the less efficient performance of moderately parasitized working horses and donkeys.[20]

Clinical syndromes caused by arteritis in the cranial mesenteric artery, aorta and iliac artery are described in other chapters. Experimentally, the migratory phase of *S. vulgaris* infection is associated with pyrexia, inappetence, depression, leukocytosis, and intermittent or continuous colic.[21] In more chronic cases there is a:

- Persistent low-grade fever
- Poor appetite
- Intermittent colic

- Poor weight gain.

Diarrhea may be present. Adult mares exposed to heavy *S. vulgaris* in late pregnancy may become very weak to the point of recumbency. On clinical examination the mucosae are pale, the heart rapid and loud and respiration moderately increased. Intestinal sounds are increased although the feces are normal. Abortion may occur and the mare usually dies. 1559 1560

The simultaneous maturation of large numbers of hypobiotic larvae induces the condition known as winter or larval cyathostominosis. This is usually characterized by rapid loss of weight, often accompanied by sudden onset diarrhea which becomes chronic. Subcutaneous edema frequently occurs. Numerous cyathostomin larvae may be passed with the feces or may be seen adhering to the glove after rectal examination. Larval cyathostominosis can occur in horses of all ages but occurs most commonly in adults under 5 years old. Unless treated early, prognosis is guarded.

27.2.15.7

CLINICAL PATHOLOGY

Examination of feces for strongylid eggs confirms the presence of adult strongyles but does not differentiate species. To do this it is necessary to hatch the eggs and examine the infective larvae.[22] This has to be done by an expert parasitologist and delays results by at least 10 d. Experimentally, specific amplification of ribosomal DNA in feces can be used for the detection and identification of strongyle infections and may lead to diagnostic tests.[23]

Hematological values, particularly reduced hemoglobin levels, erythrocyte counts and packed cell volumes are often taken as a non-specific indication of the degree of infestation with strongyles. Leukocytosis is a feature of heavy infection while eosinophilia may reflect the presence of migrating larvae. Serum analysis reveals a marked increase in beta-globulins, particularly IgG(T), and a decrease in albumin.[24]

27.2.15.8

NECROPSY FINDINGS

Adult strongyle worms may be seen attached or close to the mucosal surface. The three *Strongylus* spp. are red in color and 2–5 cm long. *Triodontophorus* and *Oesophagodontus* are smaller, up to 2 cm. Less easy to see are the small strongyles (cyathostomins) which are more slender and generally under 2 cm long with smaller buccal capsules. Because most cases of strongylosis are caused by mixed infestations with all genera, necropsy findings usually include most of the lesions characteristic of each worm.

In cases of general strongylosis, very large numbers of adult worms will be found in the cecum and colon. There may be so many that they appear to form a living cover to the contents of these organs. Catarrhal, hemorrhagic or fibrinous inflammation of the cecum and ventral colon with multiple small ulcers is associated with the emergence of cyathostomin larvae. There may be edema with excessive mucus production or numerous punctate hemorrhages. Fewer adult worms may be present in winter cyathostominosis but large numbers of larvae (several per cm^2) can be seen as brown specks in the mucosa, especially if this is illuminated from behind. Adult *T. tenuicollis* are often found in large numbers in the right dorsal colon in association with small circular hemorrhages, and they are sometimes attached in groups at the base of deep mucosal ulcers.

***Strongylus* larvae** occur in many subserous sites, especially in nodules in the intestinal wall, and the body cavities may contain an excess of blood-stained fluid. Verminous arteritis lesions of varying size associated with *S. vulgaris* are common at the root of the cranial mesenteric artery and occasionally in the iliac artery. The affected arterial wall is greatly thickened and contains loculi on its internal surface, many of which contain living larvae. Lamellated thrombi are also common at this site and these are sometimes infected. The thickening of the arterial wall often extends along the cecal and colic arteries and complete occlusion of these may be followed by gangrene of a segment of intestine. Similar lesions of arteritis may be present at the base of the aorta. Spontaneous rupture of the vessel occasionally occurs. A significant correlation has been reported between lesions in the proximal aorta and the presence of focal ischemic lesions in the myocardium.[25] These are thought to be caused by microembolization causing arteriosclerotic lesions in the myocardial arterioles.

Larvae of *S. edentatus* cause hemorrhagic tracts and nodules in the liver and adhesions and disruptions of omental architecture. Hemorrhagic nodules 1–3 cm in diameter are produced in the subperitoneal region and these are reported to cause colic and anemia.

27.2.15.9

DIAGNOSTIC CONFIRMATION

A specific diagnosis is difficult to achieve in every case. Few clinical observations or laboratory results are pathognomonic for the disease syndromes associated with strongyle infection. Often a judgment has to be made on an overall appraisal of clinical history, presenting signs and laboratory findings. For example, only 7 out of 14 cases of larval cyathostominosis were diagnosed antemortem in a series of adult horses with chronic diarrhea investigated at university referral clinics.[11]

A diagnosis of general strongylosis should be considered when poor growth, inappetence, diarrhea and some degree of anemia are the presenting signs. It is generally accepted that strongylosis is an important cause of anemia in horses. Fecal egg counts are generally high (over 800 epg) but are difficult to interpret. They have little direct correlation with worm burden as they are influenced by immunity and species composition. Also, they do not differentiate between different strongyle genera nor between these and *Trichostrongylus axei* infection of the stomach. In foals, eggs observed during the first few weeks of life are obtained by coprophagia and are not indicative of a patent infection.

The diagnosis of verminous arteritis also presents difficulty. The thickening of the cranial mesenteric artery may be palpable *per rectum*; the artery is situated below the aorta at the level of the posterior pole of the kidneys. Low serum albumin and increased beta-globulins particularly IgG(T) are the most useful laboratory tests while arteriography may demonstrate lesions in a number of arteries.[26] Transrectal ultrasonography may also be useful.[27]

In larval cyathostominosis marked weight loss, diarrhea, leukocytosis, hyperglobulinemia and hypoalbuminemia are usually seen. Peripheral edema is present in a proportion of cases. Fecal egg counts may be low or zero as it is the immature stages that cause this disease and owners have often wormed the animal before advice is sought. Consequently, serological diagnostic tests utilizing larval-antigen specific IgG(T) are under development.[28]

27.2.15.9.1

DIFFERENTIAL DIAGNOSIS

General strongylosis:

- Other causes of anemia in the horse, including:
  - Babesiosis
  - Equine infectious anemia
  - Dietary deficiency in stabled stock and the effect of racing for long periods
- Other causes of ill thrift in horses, including:
  - Ascariosis in the foal
  - Gross nutritional deficiency or agalactia in the mare.

Larval cyathostominosis:

- Other causes of chronic diarrhea including:
  - Other parasitic infections, particularly migratory strongyles
  - Granulomatous enteritis
  - Alimentary neoplasia
  - Salmonellosis
  - Chronic liver disease
  - Peritonitis
  - Sand enteropathy
  - Hyperlipidemia.

1560

1561

27.2.15.10 TREATMENT

Treatment may be targeted against immature and adult large and small strongyle worms in the lumen of the intestine, against migrating *Strongylus* larvae, particularly *S. vulgaris*, or against cyathostomin larvae in the intestinal mucosa. The latter may be developing third or fourth stage, or hypobiotic early third stage larvae. Anthelmintics vary in their efficacy against these larval stages. This influences the egg reappearance period (i.e. the time from treatment to the reappearance of eggs in the feces as new adult worm populations establish). This in turn determines the treatment interval in control programs.

For elimination of adult worms there is a wide choice of compounds and formulations for use in feed, as pastes or by tubing. Most of these however belong to just three chemical groups:

1. Avermectin/milbemycins, also known as macrocyclic lactones, (ivermectin 0.2 mg/kg, moxidectin 0.4 mg/kg)
2. Benzimidazoles (febantel 6 mg/kg, fenbendazole 7.5 mg/kg, mebendazole 5–10 mg/kg, oxibendazole 10 mg/kg)

3. Tetrahydropyrimidines (pyrantel 19 mg pyrantel embonate (pamoate)/kg or 6.6 mg pyrantel base/kg).

Cyathostomin populations resistant to the benzimidazoles are common in many countries. Such populations are sometimes, but not always, susceptible to oxibendazole. A resistant population may be slow to revert, as parasites were still resistant in one study after non-benzimidazole compounds had been used for 3 years.[29] Pyrantel-resistant strains are becoming increasingly common but there is little evidence of ivermectin resistance after 20 years of use.[30] Where resistance to any of the three groups is a problem, the choice of effective anthelmintics can be extended by use of products containing piperazine, which may be synergized with phenothiazine. An alternative to use of these products is the cautious use of selected organophosphorus compounds such as dichlorvos or haloxon (which should not be given to foals).

Mucosal cyathostomin larvae are more problematic. Publications on this topic are difficult to interpret as results may be influenced by experimental design and methodology. Moxidectin 0.4 mg/kg has activity against hypobiotic and developing third-stage larvae as well as the fourth stage.[31] Consequently, this compound has a prolonged egg reappearance period allowing a treatment interval of 13 weeks for prevention of egg output onto pasture. Ivermectin seems at best to be variable in its activity against mucosal stages[32,33] and a treatment interval of 8–10 weeks is generally recommended. Other anthelmintics at adulticidal doses have little or no effect on mucosal cyathostomin larvae and treatment intervals of 4–6 weeks are necessary during periods of heavy pasture challenge.

Fenbendazole at a single dose of 30 mg/kg or, more reliably, 7.5 mg/kg daily for 5 d is efficacious against mucosal larvae. One study has shown the latter treatment program to kill over 90% of hypobiotic and 95–99% of normally developing mucosal larvae.[34] The 5-day treatment is used in the early winter to prevent larval cyathostominosis. A second treatment may be required later in the winter if animals have continued access to contaminated pasture.

Migrating *S. vulgaris* and *S. edentatus* can be controlled with ivermectin 0.2 mg/kg or fenbendazole at 60 mg/kg (single dose) or, more reliably, 7.5 mg/kg daily for 5 d.[35] In cases of verminous arteritis, it may take some months after removal of the parasites for the lesion to resolve.[36]

27.2.15.11 CONTROL

Eradication of all horse strongyles is not feasible as infections are ubiquitous and no drug currently available can completely eliminate the mucosal larvae. Adult horses can pass substantial numbers of eggs throughout their lives, stocking densities are often high and foals usually graze with their dam. Infective larvae on grass can be long lived and there are usually few opportunities for the long-term resting or reseeding of pastures on horse farms. Consequently, the primary objective of control programs is to minimize the numbers of infective larvae accumulating on pasture. There is no pasture treatment that is economically or environmentally acceptable. The possibility of using nematophagous fungi that will destroy larvae in the feces is an exciting prospect.[37] Options for control by grazing management are limited. Alternate or mixed grazing with ruminants can reduce pasture infectively as horse strongyles will not establish in these hosts. The stomach worm *T. axei* however is a shared parasite. Removal of all horse feces from fields twice weekly is highly effective[38] provided heavy rainfall does not disperse the material. This approach can be cost effective where valuable animals are at risk or labor is relatively inexpensive. Tractor-mounted mechanical devices are available for this purpose. A further benefit of fecal removal is that the area within the field grazed by the horses is enlarged i.e. the ratio of lawn to rough increases.[39] Harrowing is effective in hot, dry conditions when eggs and larvae are quickly desiccated but at other times is likely to have a deleterious effect by spreading infective larvae.

Prophylactic chemotherapy is employed to a greater or lesser extent at most stables as land and labor constraints often limit the effectiveness of non-chemical approaches. The latter should nevertheless be used wherever possible to minimize the number of treatments needed during the year, which in turn reduces the risk of development of anthelmintic resistance. The purpose of prophylactic chemotherapy in the control of strongylosis is to prevent the output of strongylid eggs onto the pasture. Under conditions of heavy pasture challenge, regular dosing at 4–6 weeks with benzimidazoles or pyrantel, 8–10 weeks with ivermectin, or 13–16 weeks with moxidectin is necessary throughout the period of risk. Once pasture larval counts have been reduced to insignificant levels, the time between doses can be extended. Routine fecal egg counts are an important component of any control strategy as they are a direct measure of the rate at which pasture contamination is taking place. They also confirm the continuing efficacy of the drugs used and can be used to determine optimum treatment intervals.

Parasitism is a herd problem and all horses on a property should be treated simultaneously, even if they have different owners. If routine fecal examinations are performed, dosing can be restricted to those horses with significant egg counts.[40] Untreated animals then provide parasite refugia for conserving anthelmintic efficacy. As horses and ruminants generally harbor different worm parasites, disease risk can be reduced by grazing these species together or by alternating the use of paddocks between each species. As most eggs are deposited on the pasture in spring and summer in temperate regions, concentration of treatments at this time should reduce contamination and give much lower pasture larvae counts in the following autumn and winter.[5] Intensive treatment programs are often adopted on stud farms, where maximum reduction of contamination is required. Less frequent dosing may be necessary on properties with lower stocking intensities or where horses are run with other stock. As the mare is the main source of contamination for the foal, she should be treated about 2 months before foaling, again at foaling and regularly thereafter. Treatment of foals should commence at 10 weeks of age to remove small strongyles before they start to lay eggs, and should be repeated at intervals depending on the choice of drug.

1561

1562

An alternative strategy for maintaining low pasture infectivity is use of continuous low-level in-feed prophylactic therapy with pyrantel tartrate 2.64 mg/kg/d. This has been shown to control cyathostomins effectively but may be less reliable in foals against large strongyles.[41] Treated foals may be more sensitive to challenge later in life.

Delaying the onset of resistance is an important consideration in the design of any control program. The major equine anthelmintics belong to just three chemical groups and worm populations resistant to one compound are usually insusceptible to, or more tolerant of, the effects of others in that chemical group. The level of resistance in a herd can be estimated by means of the fecal egg count reduction technique (FECRT). At least six horses with high egg counts are weighed (e.g. with a weigh band) and treated with an accurately measured dose of anthelmintic. A reduction in mean egg count after 7–14 d of less than 90% is suggestive of resistance. More stringent tests are required for confirmation. Recommendations for extending the useful life of existing products similar to those listed earlier for ruminants have been published for horse anthelmintics.[42]

27.2.16 Miscellaneous roundworm infestations

27.2.16.1 *OXYURIS EQUI* (PINWORM)

Oxyuris equi is a nematode that provokes irritation of the perianal region of horses, causing them to rub and bite their tails. This can result in hair loss and sometimes physical damage to the tissues of the area. The parasite is ubiquitous but of greater prevalence in areas of high rainfall.[1]

The life cycle is direct. The mature worms are gray in color and inhabit the cecum and colon. The male is 1–2 cm long, but the female is much longer, up to 15 cm, and has a long tapering tail. When full of eggs, the female migrates down the gut and crawls onto the perianal area, where she exudes her eggs onto the skin in yellow clusters and then shrivels up and dies. An embryo develops in about 3 d within the egg which is then infective. Eggs may be licked off the skin and swallowed or they may eventually fall to the ground. They resist desiccation, may become airborne in dust and remain viable in stables for long periods. Transmission then occurs via contaminated feedstuffs.

Diagnosis is by detection of operculated eggs, slightly flattened on one side, on transparent adhesive tape that has been pressed against the perianal skin and then placed on a microscope slide for examination, or by the chance observation of an adult worm in the feces.

Treatment comprises the application of a mild disinfectant ointment to the perianal region and the administration of ivermectin, moxidectin, any of the newer broad-spectrum benzimidazoles or pyrantel at the standard dose rate for horses. Piperazine salts are also effective.

27.2.16.2 *STRONGYLOIDES* (THREADWORM)

Farm animals in many countries are exposed to infection with the nematode genus *Strongyloides*. Disease outbreaks occur in young pigs, foals, calves, and lambs but the overall economic importance of this parasite does not appear to be very great. Different

species occur in each host: *Strongyloides ransomi* in pigs, *S. westeri* in horses, and *S. papillosus* in sheep and cattle. All are parasites of the small intestine. They are thread-like and less than 1 cm in length.

Only female worms are present in the intestine and so eggs are produced by parthenogenesis. The eggs are thin shelled and contain an embryo. The larvae that hatch out may develop into infective or non-parasitic forms. The latter become free-living males and females which live in decaying organic material and produce fertilized eggs that give rise to infective larvae. Transmission occurs when infective larvae enter the host either by ingestion or by skin penetration. In older animals they accumulate in subcutaneous tissues and migrate to the mammary gland when lactation starts.[1,2] Neonates are thereby infected via the milk and egg-laying females may be present in the intestine from about 1 week after birth. Infective larvae penetrating the skin of young animals travel via the blood to the lungs, where they break into alveoli, ascend the air passages to the pharynx and are then swallowed.

Diarrhea in young animals is the most common clinical sign but the passage of massive numbers of larvae through the skin may also provoke dermatitis. Experimental infections in calves cause pallor and coughing[3] but cases of sudden death without previous symptoms have been ascribed to heavy burdens with many migratory larvae.[4] In bulls, balanoposthitis may be seen. In lambs, dermatitis, pulmonary hemorrhage, and enteritis occur. Sheep may also develop lameness or be more susceptible to foot rot when subject to heavy infestations. Experimental infection of young goats produced transient diarrhea, dehydration, cachexia, gnashing of teeth, foaming at mouth, anemia and nervous signs.[5] Pigs may show anorexia, listlessness and anemia but diarrhea is the principal clinical sign. Infestation in pigs has been shown to reduce intestinal enzyme activity, to increase intestinal plasma and blood loss and to reduce protein synthesis in the liver.[6] In foals, high egg counts may be recorded in apparently healthy animals but may coincide with the onset of diarrhea (independent of the first heat of the mare) in other individuals. Episodes of frenzy in foals lasting approximately 30 min have been attributed to percutaneous larval invasion.[7,8] Within 2 d skin lesions developed on the lower limbs which persisted for 2–3 weeks.

1562
1563

Most broad-spectrum anthelmintics are effective in eliminating this parasite. In foals, ivermectin is used at the standard equine dose but elevated doses of fenbendazole (50 mg/kg) and oxibendazole (15 mg/kg) are needed. The treatment of mares with ivermectin on the day of parturition did not prevent transmammary transmission but markedly reduced

egg counts in the foals. Treatment of infected sows was effective in removing arrested larvae from the subventral fat.[9] Use of the ivermectin controlled-release bolus in lambs prevented establishment of intestinal *Strongyloides* infections.[10]

Control depends on the elimination of warm, moist areas such as damp litter or bedding, suitable for parasite multiplication.

27.2.16.3

TRICHURIS (WHIPWORM)

Three species of whipworms are found in ruminants: *Trichuris ovis*, *T. discolor*, and *T. globulosa*, while *T. suis* occurs in pigs. Whipworms in farm livestock are usually considered to be relatively innocuous. Indeed, induced *T. suis* infections are being evaluated in human medicine for amelioration of chronic inflammatory bowel disease, since whipworm induced Th2 immune responses dampen harmful Th1 activity in some patients.[1] Heavy infestations can nevertheless produce serious disease with diarrhea and dysentery[2,3] and the mortality rate can be high in recently weaned pigs. Severely affected animals are anorexic and rapidly lose weight. The feces may contain blood-stained mucus and strips of necrotic mucosa. The nematodes lie with their thin anterior end superficially embedded in the wall of the cecum and in heavy infections the colon may also be involved. The activities of the worms produce little tissue reaction *per se* but enable micro-organisms in the gut microflora to become invasive. This is the main cause of the severe

inflammation and clinical signs associated with whipworm infestation.[4] A synergy has also been demonstrated between *T. suis* and *Campylobacter jejuni*.[5]

The life cycle is direct. The eggs are very resistant to external environmental conditions and can survive for up to 6 years in old pigsties, and for at least 2 years on pasture in the south of England.[6] An infective larva develops inside the egg but a relatively high temperature is required for rapid growth. In temperate climates, embryonation of *T. suis* eggs may take more than 1 year.[7] When swallowed by a suitable host, the eggs hatch and develop to mature adults in about 12–20 weeks after infection in lambs and goats and 7 weeks in pigs. The disease in sheep occurs most commonly after hot, dry weather, which effectively cleanses the pasture of other nematode larvae but the resistant *Trichuris* spp. eggs survive and are ingested when the sheep eat close to the ground to obtain grain given as drought feed.

Diagnosis depends on detection in the feces of the yellow oval eggs, which have a transparent plug at each end. The eggs are heavier than many others and do not always float well in saturated salt (NaCl) solution. An alternative flotation fluid such as zinc sulfate or sugar is more reliable. At necropsy, the adult worms which are 2–5 cm long are easily recognized by their whip-like appearance – the anterior third is much thinner than the handle-like posterior end.

Chemotherapy may give variable results as *Trichuris* is only distantly related to the usual target species. Most modern broad-spectrum anthelmintic compounds can be used but not all are active against immature forms and repeat dosing may be necessary.

27.2.16.4

CHABERTIA

Chabertiosis of sheep, goats, and cattle is associated with *Chabertia ovina* a worm 1–2 cm in length, which inhabits the colon and causes a clinical syndrome similar to that of oesophagostomosis. Disease is mainly seen in sheep in colder areas during the winter months. Infections do occur in cattle but are rarely pathogenic. The lifecycle is direct and resembles that of other strongylid worms. Infective larvae are relatively resistant to cold and heavy infestations may occur in mild winters. After ingestion, larvae undergo a period of development in the wall of the small intestine before passing to the cecum and then to the colon. Unlike *Oesophagostomum*, the larvae do not cause any significant damage. The infection becomes patent in about 7 weeks.

Clinical signs are first seen when immature adults start to attach to the mucosa about 26 d after infection.[1] Soft blood flecked feces with excess mucus are passed. A protein-losing enteropathy occurs with lowered blood albumin and weight loss. Death may occur in heavy infections.[2] Fecal egg counts do not always correlate well with clinical signs as these may occur before the worms mature. Immunity can also reduce the fecundity of adult *Chabertia*.

Changes at necropsy are thickening, edema and petechiation of the wall of the colon with blood sometimes present in the intestinal contents. The worms, which are easily recognized by their large buccal cavities, are usually confined to the first 25–30 cm of the coiled colon, except in very heavy infections. The number of worms present is often surprisingly small and severe morphological changes may be evident with only five to 10 worms. More than 100 worms is considered to be a heavy infestation. All the newer broad-spectrum anthelmintics are effective against *C. ovina*.

27.2.16.5

HABRONEMA AND *DRASCHIA*

These gastric nematodes of the horse are described in ‘Summer sores in horses'.

27.2.16.6

MACRACANTHORHYNCHUS (THORNY-HEADED WORM)

Macracanthorhynchus hirudinaceus is included in this section for convenience but it is not a nematode. It belongs to a different phylum, the acanthocephalans. These resemble roundworms in appearance but in some ways are more similar to tapeworms as they lack, for example, a digestive tract. The name ‘thorny-headed worm' denotes the hook-covered proboscis which they all possess.

M. hirudinaceus infestations in pigs are not usually heavy and cause relatively little loss. 1563
The worms have thick bodies (0.5–1.25 cm), are long (up to 38 cm) and transversely 1564
wrinkled. They inhabit the small intestine and pass eggs which are very resistant to environmental stress and survive for up to 2 years. The lifecycle is indirect with a variety of beetles acting as intermediate hosts. Transmission occurs when a pig eats an infested grub or adult beetle and eggs are passed some 2–3 months later. The female worm is a prolific egg layer and lives in the host for about 1 year.

Heavy infestations cause slow growth or loss of body weight. The head of the worm pushes deeply into the intestinal mucosa and causes nodules that are clearly visible from the serous surface. Occasional deaths may occur due to intestinal perforation. Sedimentation techniques are better than flotation methods for detecting eggs in feces. Treatment is rarely given as the condition is usually only diagnosed at necropsy. Ivermectin given in the feed to provide 0.1 or 0.2 mg/kg for 5 d gives good results.[1] A single dose of doramectin is only partly effective.[2] Control, if necessary, involves suitable disposal of pig manure and avoidance of contact with the intermediate hosts, beetles.

27.3 Nematode diseases of other organs

27.3.1 Lungworm infestation

27.3.1.1 LUNGWORM IN CATTLE

27.3.1.1.1 Synopsis

27.3.1.1.1.1 Etiology

The nematode *Dictyocaulus viviparus* (the bovine lungworm).

27.3.1.1.1.2 Epidemiology

Disease seen mostly in dairy calves; immunity develops relatively quickly but cattle will succumb if exposed to overwhelming numbers of infective larvae while grazing.

27.3.1.1.1.3 Signs

Coughing, tachypnea, dyspnea.

27.3.1.1.1.4 Clinical pathology

Characteristic larvae in feces (but not present during all stages of disease); eosinophilia; enzyme-linked immunosorbent assay (ELISA) tests for serum antibodies.

27.3.1.1.1.5 Lesions

Large volumes of consolidation in diaphragmatic lobes of lung, emphysema, worms up to 8 cm long in bronchi (only in patent phase of disease).

27.3.1.1.1.6 Diagnostic confirmation

Clinical pathology as above; at necropsy, distribution of lesions in lungs and demonstration of worms in bronchi.

27.3.1.1.1.7

Treatment

Benzimidazoles and avermectins/milbemycins are active against all parasitic stages of *D. viviparus*; the latter also have a persistent protective effect; levamisole also used.

27.3.1.1.1.8

Control

Vaccination; early season anthelmintic prophylactic programs using suitable intraruminal boluses or multiple doses of avermectins/milbemycins; keep susceptible animals off potentially dangerous pasture.

27.3.1.1.2

ETIOLOGY

The nematode *Dictyocaulus viviparus* is the only lungworm of cattle. The disease it causes has many local names including:

- Parasitic bronchitis
- Verminous pneumonia
- Verminous bronchitis
- Husk
- Hoose.

Bovine lungworm has a very wide distribution through temperate and cold areas and, depending on climatic conditions and season, can cause serious losses.[1] The disease reaches its greatest importance in mild, damp regions of the British Isles and parts of western Europe. Deer carry similar parasites, including *D. eckerti* and *D. capreolus*. It is uncertain whether deer play a role in the transmission of *D. viviparus* but lungworm species are generally host specific.[2]

27.3.1.1.3

LIFECYCLE

Adult lungworms live in the trachea and bronchi. The females are prolific egg producers and it has been estimated that a single infested calf may contaminate a pasture with 33 million larvae. The eggs are coughed up and swallowed. They hatch in the air passages or alimentary canal and larvae are passed in the feces. These develop in the dung pat

through to the infective third stage, which is protected by cuticles retained from both first and second molts. As the ensheathed larvae cannot feed, glycogen granules are stored in the intestinal cells. Moisture is essential for the survival and development of the larvae and a moderate temperature of 18–21°C (65–70°F) permits their full development to the infective state in 3–7 d. Larvae survive best in cool, damp surroundings, especially when the environment is stabilized by the presence of long herbage or free water. Under optimum conditions, larvae may persist for over 1 year. They can overwinter in climates as cold as Canada and Germany. When warmer spring weather arrives, the larvae resume their motility but quickly die once their food stores are depleted.

Transmission occurs when cattle ingest third-stage larvae while grazing. These migrate through the intestinal wall to reach the mesenteric lymph nodes. From here they pass via the lymphatics to the venous bloodstream and through the heart to the lungs, where they break into the alveoli. They migrate up the bronchioles to their predilection site in the larger air passages and start to lay eggs some 3–4 weeks after infestation. Most adult worms succumb to immune expulsion within a few weeks. These events determine the progression of the clinical syndrome and their approximate timing is as follows[3]:

2. Penetration phase (ingestion to arrival of larvae in lung), days 1–7
2. Prepatent phase (larvae in lung), days 7–25
3. Patent phase (mature worms in lung) days 25–55
4. Postpatent phase (lungworms disappearing from lung), days 55–70.

27.3.1.1.4

EPIDEMIOLOGY

Bovine parasitic bronchitis is a sporadic and largely unpredictable disease. This is because immunity develops more quickly than is the case with many other nematode infections, but nevertheless can remain incomplete for many weeks and may wane in the absence of reinfection. In most grazing seasons, immunity will develop fast enough to protect calves against the accumulating numbers of infective larvae on the grass. The farmer may not even realize that his land is contaminated. Clinical outbreaks occur when weather patterns, management or other factors result in sudden exposure to a pasture challenge sufficient to overwhelm any immunity that has already developed. In comparison with the gastrointestinal nematodes of cattle, relatively few worms (i.e. a few hundred or thousand) are required to produce clinical signs. Thus, the disease is almost entirely confined to grazing cattle and occurs most frequently in young animals in

their first year on grass, although outbreaks are becoming more common in adults. The epidemiology of lungworm disease is largely concerned with factors determining the number of infective larvae on the pasture and the rate at which they accumulate.

Infective *D. viviparus* larvae are relatively inactive and are incapable of traveling more than 5 cm from the dung pat. Factors that disperse the larvae more widely over the pasture include mechanical spread by:

1564

1565

- Rain
- Earthworms
- Wheeled vehicles
- Human and animal feet.

A fungus, *Pilobolus*, plays a particularly important role in this process and can transfer larvae across field boundaries. Fungal spores on grass pass through the grazing animal and germinate in the feces. *Dictyocaulus* larvae climb onto the sporangium (fruiting body), which fills with water and bursts, propelling the fungal spore and the lungworm larvae for distances of up to 3 m.[4]

Dairy calves are most vulnerable to lungworm disease as they are often reared indoors until 4–5 months of age and then placed on paddocks grazed each year by successive calf crops. If the paddocks are heavily contaminated, acute disease may occur in 1 week or so. Usually however only sufficient larvae survive the winter to induce low-grade asymptomatic infections in the susceptible calves, which then start to recontaminate the pasture and recycle the infection. With the high stocking densities commonly used, pasture challenge can reach pathogenic levels within 2–4 months. This model does not satisfactorily explain all outbreaks and it has been suggested that larvae may be washed into the soil to emerge later, e.g. onto hay aftermath.[5] Beef calves at grass with their dams are less likely to be affected as this system provides fewer opportunities for large numbers of larvae to accumulate, but outbreaks can occur particularly after weaning in the autumn.

In older animals larvae ingested in the autumn become hypobiotic and resume their development in the following spring. This event occasionally causes disease in housed cattle[6] but such infections are usually asymptomatic and provide a source of pasture contamination when these carrier animals are put out to graze. This is thought to be the

main source of infection in more severe climates where overwintering larvae may not survive on the pasture, but carrier animals have also been incriminated in disease outbreaks in, for example, Louisiana in the United States.[7]

Immunity to reinfestation occurring after initial exposure to *D. viviparus* is variable in degree and duration. It normally provides protection during the first grazing season and is boosted by exposure to overwintered larvae at the beginning of each subsequent grazing season. Cattle removed from infected pastures for long periods can suffer clinical disease when re-exposed. Recently, the number of outbreaks of parasitic bronchitis in yearling and adult cattle in the United Kingdom, Denmark and some other countries has been rising.[8] Reasons for this are speculative but include:

- A decline in the use of vaccination
- Changes in weather patterns and management systems
- Use of highly effective anthelmintic strategies in the first grazing season that may prevent adequate antigenic exposure.

27.3.1.1.5

PATHOGENESIS

Migrating *D. viviparus* larvae provoke little damage until they reach the lungs. Thereafter, passage of larvae up the bronchioles causes them to become blocked by mucus, eosinophils, and other inflammatory cells, leading to collapse of the alveolae that they supply.[3] Coughing and dyspnea occur if a sufficiently large volume of lung tissue is affected. This is accompanied by pulmonary edema and interstitial emphysema. As no structural damage has yet occurred, treatment at this stage in the disease produces an immediate clinical response. Later however when mature parasites are in the major bronchi, eggs and fragments of worms killed by immunity are aspirated and provoke a foreign body pneumonia. Secondary bacterial infections establish and sequelae such as bronchiectasis occur. Such lesions are slow to resolve and treated animals will require a long recovery period. Later still, once all or most of the worms have been expelled, the alveolar lining cells of some 25% of recovering animals become cuboidal and non-functional. The reason for this is unknown but may be a response to substances released by the dead worms. As this reaction is irreversible many animals affected in this way will die.

The response of the lung varies widely depending on the number of larvae ingested, the nutritional status and age of the host, and whether or not it is exposed to lungworm infection for the first time. Vaccinated animals or those that have recovered from clinical or sub-clinical infection may cough and even become tachypneic if grazed on contaminated pasture.[9] This is known as the ‘re-infection syndrome' and occurs as many larvae reach the lungs before succumbing to the immune response. Exposure of older previously infected animals to massive challenge may invoke a severe or fatal hypersensitivity reaction.[10]

27.3.1.1.6

CLINICAL FINDINGS

Outbreaks vary in severity from sporadic coughing with no apparent production loss to acute cases with a rapidly fatal outcome. Individuals within a group are usually affected to varying degrees. Poorly nourished animals appear less able to withstand lungworm infection. Nevertheless, it is not unusual for severe infestations to be fatal in well-fed calves.

Acute cases have rapid shallow abdominal breathing of sudden onset that may reach a rate of 60–100 breaths/min. There is a frequent bronchial cough, a slight nasal discharge, a temperature of 40–41°C (104–105°F) and a heart rate of 100–120 bpm. The animal is bright and active and will attempt to eat, although respiratory distress often prevents this. Progress of the disease is rapid and within 24 h dyspnea may become very severe, accompanied by mouth breathing with the head and neck outstretched, a violent respiratory heave and grunt, cyanosis and recumbency. On auscultation, lung consolidation is evidenced by loud breath sounds and crackles are heard over the bronchial tree. The crackling of interstitial emphysema commences over the dorsal two-thirds of the lung but is never as evident as in less acute cases. Fever persists until just before death, which usually occurs in 3–14 d and is greatly hastened by exercise or excitement. The case – fatality rate in this form of the disease is high, probably of the order of 75–80%.

Subacute disease is more common in calves than the very acute form. The onset is usually sudden, the temperature is normal or slightly elevated and there is an increase in the rate (60–70 breaths/min) and depth of respiration. An expiratory grunt is heard in severe cases and expiration may be relatively prolonged. There are frequent paroxysms of coughing. The course of the disease is longer, 3–4 weeks, and auscultation findings vary widely with the duration of the illness and the area of lung involved. In general,

there is consolidation and bronchitis ventrally, and marked emphysema dorsally. Affected animals lose weight very quickly and are very susceptible to secondary bacterial bronchopneumonia. The mortality rate is much less than in the acute form but many surviving calves have severely damaged lungs. Consequently, they may remain stunted for long periods and breathing may be labored for several weeks. Some surviving calves may show a sudden exacerbation of dyspnea around 7–8 weeks after the initial onset of disease. In these relapsed cases the prognosis is grave.

Adult dairy cattle are usually immune but sporadic outbreaks do occur due to waning immunity. Mortality is low but morbidity can be high with reduced milk yields causing significant economic loss. Coughing is a constant feature but other clinical signs are variable and may include dyspnea, nasal discharge, and weight loss. Sudden exposure of immune adults to massive challenge can cause severe interstitial pneumonia.

1565

1566

27.3.1.1.7

CLINICAL PATHOLOGY

The presence of *D. viviparus* larvae in feces confirms lungworm infestation but their absence does not necessarily exclude the possibility of parasitic bronchitis. No larvae will be passed in the early stages of disease when the causal worms are still immature, nor will they be a constant finding when partially immune animals (e.g. dairy cows) succumb to challenge. In general, larvae can be found about 12 days after signs appear, i.e. around 24 days after infestation occurs. They are few in number at first but may become more numerous later.

Enzyme-linked immunosorbent assay (ELISA) tests using adult or larval worm antigen to demonstrate exposure to lungworm infection are available in some countries.[8] Care is required with interpretation as antibodies to adult antigen may not be detectable until several weeks after primary challenge[11] and do not correlate with the immune status of the animal. Eosinophilia is a fairly consistent finding but not pathognomonic.

An alternative method, if disease is suspected but the lungworms are still in the prepatent stage, is to examine pasture clippings for larvae. This is a laborious procedure because large amounts of herbage (0.5–1 kg) must be used and the yield of larvae is low.

27.3.1.1.8

NECROPSY FINDINGS

Adult *D. viviparus* are up to 8 cm long and easily seen when the trachea and bronchi are cut open. Worms may also be recovered by lung perfusion.[12] Up to several thousand

may be present in severely affected animals. In prepatent disease however careful microscopic examination of bronchial mucus is necessary to find larvae. Adult worms may be few or absent if the case is of sufficient duration for immune expulsion to have taken place.

In acute cases, morphological changes include:

- Enlargement of the lungs due to edema and emphysema
- Widespread areas of collapsed tissue of a dark pink color
- Hemorrhagic bronchitis with much fluid filling all the air passages
- Enlargement of the regional lymph nodes.

Histologically, the characteristic signs are:

- Edema
- Eosinophilic infiltration
- Dilation of lymphatics
- Filling of the alveoli and bronchi with inflammatory debris
- Larvae in the bronchioles and alveoli.

In subacute cases, interstitial emphysema is usually gross. Areas of dark pink consolidation are present in the diaphragmatic lobe and may also occur in other lobes. They can occupy two-thirds of the lung volume. There is froth in the bronchi and trachea. The regional lymph nodes are enlarged. Histologically, eggs and larvae can be seen in the air passages, the bronchial epithelium is much thickened, the bronchioles are obstructed with exudate and the alveoli show epithelialization and foreign-body giant-cell reaction.

The reinfection syndrome is characterized by the presence of numerous 5 mm gray-green nodules formed by lymphoreticular cells clustering around dead larvae.

27.3.1.1.9

DIAGNOSTIC CONFIRMATION

D. viviparus larvae may be demonstrated by placing feces on a fine sieve or dental gauze on the top of a water-filled funnel (the Baermann technique). The larvae that swim into

the water and collect at the bottom of the funnel are less than 0.5 mm long, sluggish and often appear curved or coiled. Their most important diagnostic feature is the presence of easily visible refractile granules in the intestinal cells. As not all animals will be shedding larvae, samples should be taken from all, or at least a representative proportion of the group. Grass samples are washed in water with a surfactant and the sediment Baermannized as above. A technique which effectively separates larvae from plant debris by migration through agar gel has been reported.[13] Gathering grass close to dung pats maximizes chances of finding larvae. Cattle with parasitic bronchitis are likely to have eosinophilia and serological tests can be used to rule out some other respiratory diseases such as infectious bovine rhinotracheitis (IBR).

In view of the uncertainties associated with laboratory tests for parasitic bronchitis and the need for prompt treatment, diagnosis often has to be based on clinical history, signs and auscultation. Affected animals have usually grazed alongside potential carriers or had access to pasture previously used by susceptible calves or older carrier animals. The timing of the outbreak may coincide with that expected from recycling of an infection initiated by overwintered larva (often 2–4 months after turnout) or recent exposure to heavily contaminated land. Many of the clinical signs of parasitic bronchitis are common to pneumonias of bacterial and viral origin. One feature which may be of value in differentiation is the relative softness and paroxysmal nature of the cough in parasitic infection.

27.3.1.1.9.1

DIFFERENTIAL DIAGNOSIS

- Bacterial bronchopneumonia
- Acute and chronic interstitial pneumonia
- Viral pneumonia
- Acute interstitial pneumonia (fog fever)
- Heavy infestations with ascarid larvae on pastures contaminated with pig feces.

In adult cattle, the major problem in diagnosis is to differentiate the acute form of the disease from acute interstitial pneumonia due to other causes. Clinically, the diseases are indistinguishable, and a history of movement onto a new pasture 1–2 weeks before the onset of the disease may be common to both. It is necessary to demonstrate *D. viviparus*

antibodies in blood, worms at necropsy, and larvae in the herbage or in the feces of animals that previously grazed the pasture.

27.3.1.1.10

TREATMENT

Anthelmintics may be used prophylactically to prevent disease from occurring, as a curative treatment once disease strikes, or to prevent reinfection following an outbreak. Avermectins and milbemycins are particularly useful for prophylaxis and prevention of reinfection as they are not only highly effective against the lungworms present in the animals at the time of treatment but have prolonged activity against subsequent incoming larvae. The duration of this persistent effect varies with compound and formulation.

Most modern broad-spectrum drugs are active against *D. viviparus*. Dosage rates and label claims vary from country to country according to local conditions and regulatory requirements. Avermectins and milbemycins (macrocyclic lactones) are particularly potent against immature and mature stages; doses of ivermectin, for example, as low as 0.05 mg/kg are effective. At commercial dose rates, ivermectin by injection or as a pour-on formulation provides residual protection for up to 28 d; corresponding figures are up to 35 d for doramectin by injection and 42 d both for doramectin as a pour-on formulation and moxidectin by either route of administration. These compounds are given at 0.2 mg/kg by injection and 0.5 mg/kg as a pour-on formulation. Eprinomectin is the compound of choice for adult dairy cattle as it has a nil milk withdrawal period[14] and provides residual protection of up to 28 d when given topically (0.5 mg/kg). Albendazole 1566
(7.5 mg/kg), febantel (7.5 mg/kg), fenbendazole (7.5 mg/kg), netobimin (7.5 mg/kg), and 1567
oxfendazole (4.5 mg/kg), which are given orally, are active against all stages of the parasite but have no residual activity. Levamisole (oral or injection – 7.5 mg/kg; pour on – 10 mg/kg) also has activity against lungworm but no persistent effect.

Sustained-release intraruminal devices (‘boluses') provide extended periods of protection. For example, fenbendazole is released for up to 140 d from one bolus. There are also pulse release boluses containing oxfendazole which release five or six anthelmintic doses at 3-week intervals. Most boluses normally protect against disease but may allow some worms to establish (in the case of the fenbendazole bolus) or to reach the lungs between pulses (oxfendazole bolus), which may allow immunity to develop.

For veterinarians in the field the outcome of therapeutic treatment is often unpredictable as it depends on the amount of structural damage in the lungs. Best results

are obtained early in the course of disease when most pathological changes can be quickly resolved. In severe cases, treatment may initially exacerbate clinical signs as the death and disintegration of many worms in the air passages releases antigens and adds to the mass of foreign material that can be aspirated. Because of animal welfare considerations and the high risk of mortality, anthelmintic treatments are often combined with an antihistamine or non-steroidal anti-inflammatory drug (NSAID) such as flunixin to reduce the severity of the reaction to the larvae and an antibiotic or sulfonamide to prevent secondary bacterial infection. Severely affected animals should be brought indoors for nursing and all other members of the group removed from the contaminated pasture and placed on clean grazing ground.

27.3.1.1.11

CONTROL

Two major strategies of control derive from the premise that the main factor governing the occurrence of disease is the density of *D. viviparus* larvae on pasture grazed by susceptible cattle. Firstly, cattle grazing potentially contaminated pasture can be protected by vaccination or anthelmintic cover. Alternatively, steps can be taken to ensure that pastures are safe for grazing. This is usually achieved by prophylactic anthelmintic programs, but delaying spring turnout until overwintered larvae have died away is a theoretical option on organic farms.[15]

Sensible grazing management is important in all systems but cannot be relied upon, *per se*, for controlling parasitic bronchitis in view of the unpredictable nature of the disease. Although natural immunity provides adequate protection on many farms, it cannot be accurately measured nor predetermined.[16] With the possible exception of beef suckler systems, calves should not be run with or follow older cattle as these may harbor asymptomatic patent infections and contaminate the pasture. An important consideration is that clean pasture can be contaminated by larvae from neighboring fields carried on windborne fungal spores (see epidemiology paragraph earlier). Although the numbers of larvae spread in this way are likely to be small, they can initiate the epidemiological cycle culminating in disease after some weeks.

Vaccination of calves with two doses of 1000 infective larvae attenuated by irradiation is a long-established and effective method of preventing disease. Only healthy calves should be vaccinated and they should be at least 8 weeks old. The vaccine is given 6 and 4 weeks prior to turnout. Exposure to lightly contaminated pasture will boost immunity but low-grade patent infections may develop in some animals. Vaccinated and non-

vaccinated calves should not be grazed together as the former may contaminate the pasture enabling lungworm to cycle through the susceptible animals. The vaccine gives a high level of protection under most conditions but vaccinated calves should not be put onto heavily contaminated pasture. Coughing may occur when immune responses kill lungworm larvae in the lungs. Overt disease can occur in cases of overwhelming challenge. To avoid such problems on severely affected farms, vaccinated calves should be allowed only gradual access to pasture.

In some endemic areas, for example in the south of Ireland which has mild winters and an early start to the grazing season, the ideal vaccination program described earlier may be inconvenient and it is possible, by cautiously avoiding periods when massive pasture contamination are likely to occur, to vaccinate at pasture.[17] Calves are sometimes vaccinated at less than 8 weeks old to allow spring-born calves to graze during late summer and autumn[18] but optimal protection may not be afforded in all cases.

Strategic anthelmintic programs provide an alternative to vaccination. The aim is to suppress the infection initiated by overwintered larvae and thereby prevent subsequent contamination of the pasture. This can be done by application of a suitable intraruminal bolus at or just before spring turnout or by giving two or three doses of an avermectin/milbemycin during the early grazing season. These systems are designed to control parasitic gastroenteritis as well as lungworm. Clinical field experiments have demonstrated good results with ivermectin, fenbendazole, and oxfendazole boluses and with ivermectin treatments given at 3, 8, and 13 weeks after turnout, or doramectin administered at turnout and again 8 weeks later. Calves may become vulnerable after the period of anthelmintic cover if pasture contamination occurs (e.g. because of fungal spread). An extra anthelmintic treatment may be indicated in regions with a very long grazing season. Calves which are exposed to infection but protected by chemoprophylaxis during their first grazing season generally have substantial resistance to reinfection in their second year.[19] Nevertheless, field experiments have shown that immunity can be compromised to a degree related to the level of protection provided.[20] There is concern that such intensive treatment may provoke anthelmintic resistance but no resistant strains of *D. viviparus* have yet been reported.

27.3.1.2 LUNGWORM IN HORSES

27.3.1.2.1 Synopsis

27.3.1.2.1.1 Etiology

The nematode parasite *Dictyocaulus arnfieldi*.

27.3.1.2.1.2 Epidemiology

Infection is by ingestion of larvae on herbage; donkeys and foals shed most larvae, but adult horses can perpetuate lifecycle.

27.3.1.2.1.3 Signs

Chronic cough in adult horses.

27.3.1.2.1.4 Clinical pathology

Eggs or larvae in feces (but often absent in affected adults); eosinophils in tracheal mucus.

27.3.1.2.1.5 Lesions

Discrete areas of hyperinflation in lung tissue.

27.3.1.2.1.6 Diagnostic confirmation

Response to treatment if no eggs/larvae in feces.

27.3.1.2.1.7 Treatment

Ivermectin, fenbendazole (elevated dose); mebendazole over 5 d for donkeys.

27.3.1.2.1.8 Control

Avoid grazing donkeys and horses on same pasture.

27.3.1.2.2

ETIOLOGY

Lungworm disease in horses is associated with the nematode parasite *Dictyocaulus arnfieldi*.

27.3.1.2.3

LIFECYCLE

The lifecycle of *D. arnfieldi* is direct and is almost identical to that of *D. viviparus* except that the eggs do not hatch until shortly after they are passed in the feces.

27.3.1.2.4

EPIDEMIOLOGY

Infestations with *D. arnfieldi* are recorded more commonly in donkeys than in horses and the former are considered to be the more normal host. Patent infections may persist in donkeys throughout their lives but in horses are generally confined to foals. These animals therefore provide the most important sources of pasture contamination. Nevertheless, a small proportion of infected adult horses shed low numbers of eggs and this may be sufficient to perpetuate the lifecycle even in the absence of donkeys and foals. As with *D. viviparus*, larvae can cross field boundaries by fungal transfer.

27.3.1.2.5

PATHOGENESIS

Adult worms are found in the smaller bronchi which they almost completely block.[1] In adult horses however, few larvae reaching the lungs develop to this stage. Bronchioles in affected areas are surrounded by dense infiltrations of inflammatory cells, the epithelium becomes hyperplastic and excessive mucus is produced. The consequent interference with air flow leads to patches of hyperinflation in the lung tissue.

27.3.1.2.6

CLINICAL FINDINGS

Lungworm disease in horses is characterized by a chronic cough. Experimental infections produce an afebrile condition with coughing, increased respiratory rates and forced expiration being most intense during weeks 3–5 after infection. Thereafter the signs decrease in severity but coughing may persist for several months.[2] Heavy infestations in donkeys do not cause clinical illness. Horse foals may also be symptomless although some show clinical signs.

27.3.1.2.7

CLINICAL PATHOLOGY

Characteristic eggs may be found in the feces of a small proportion of cases. Eosinophils and sometimes eggs or larvae may be demonstrated in tracheal mucus.[3]

27.3.1.2.8

NECROPSY FINDINGS

The most obvious lesions at necropsy are discrete patches of overinflation.

27.3.1.2.9

DIAGNOSTIC CONFIRMATION

D. arnfieldi eggs in fresh feces are oval, thin shelled and contain a larva.[4] As the eggs may have hatched before arrival at the laboratory, it is usual to harvest larvae with the Baermann technique. The larvae resemble those of *D. viviparus* but the tail ends in a small spine. As many clinical cases are non-patent and as tracheal mucus is difficult to sample, confirmation of diagnosis is often dependent on response to treatment.

27.3.1.2.9.1

DIFFERENTIAL DIAGNOSIS

- Recurrent airway obstruction (heaves)
- Pulmonary abscessation and pneumonia
- Inflammatory airway disease.

27.3.1.2.10

TREATMENT

Ivermectin at the standard equine dose is highly effective against immature and mature stages. For donkeys, mebendazole may be used at 15–20 mg/kg daily for 5 d, but this should not be attempted within the first 4 months of pregnancy.

27.3.1.2.11

CONTROL

Donkeys and horses should not be grazed on the same pasture. If this is impossible, the former should be treated regularly for lungworm. If there is a problem in a closed herd of adult horses, individuals with patent infection can be identified by fecal screening and treated.

27.3.1.3

LUNGWORM IN SHEEP AND GOATS

27.3.1.3.1

Synopsis

27.3.1.3.1.1

Etiology

The nematode parasites *Dictyocaulus filaria*, *Muellerius capillaris*, and *Protostrongylus rufescens*.

27.3.1.3.1.2

Epidemiology

Infective *D. filaria* larvae are found on grass but *M. capillaris* and *P. rufescens* are transmitted when molluscan intermediate hosts are accidentally ingested by grazing animals.

27.3.1.3.1.3

Signs

D. filaria and *P. rufescens* can cause bronchitis and loss of condition. *M. capillaris* is asymptomatic in sheep but may be pathogenic in goats.

27.3.1.3.1.4

Clinical pathology

Characteristic larvae in feces.

27.3.1.3.1.5

Lesions

D. filaria and *P. rufescens*: scattered patches of consolidation; *M. capillaris*: small fibrous nodules up to 5 mm in diameter.

27.3.1.3.1.6

Diagnostic confirmation

Characteristic larvae in feces.

27.3.1.3.1.7

Treatment

Avermectins/milbemycins, benzimidazoles or levamisole.

27.3.1.3.1.8

Control

No specific measures available.

27.3.1.3.2

ETIOLOGY

Infestations with the nematode *Muellerius capillaris* are ubiquitous. *Dictyocaulus filaria* and *Protostrongylus rufescens* are encountered sporadically. *Cystocaulus ocreatus* and *Neostrongylus linearis* have been recorded in some countries.

27.3.1.3.3

LIFECYCLE

D. filaria has a direct lifecycle like that of *D. viviparus* in cattle. The lifecycles of the other (protostrongylid) species are similar except that they have different predilection sites in the lung and have indirect lifecycles with molluscan intermediate hosts. Transmission occurs when infected slugs or snails are accidentally ingested during grazing.

27.3.1.3.4

EPIDEMIOLOGY

D. filaria infestations in sheep appear to follow the same pattern as those of *D. viviparus* in calves but the number of lungworms is usually low. The third-stage larvae are long-living in damp, cool surroundings. The lambs of one season are the main source of infection for the next season's lambs, but larvae passed by ewes and yearlings also contribute to pasture contamination. The prevalence of infection is low in spring and summer but rises rapidly in the autumn and winter, when most clinical cases are seen. Warm, wet summers give rise to heavier burdens in the following autumn and winter.[1] Immunity after natural exposure is strong and durable in sheep but less so in goats.[2]

1568

1569

M. capillaris infestations in sheep have been recorded from most parts of the world and in many temperate areas almost all sheep are infected. Massive invasion with larvae is uncommon because the intermediate hosts are not usually ingested in large numbers nor are they grossly infested with larvae. Massive infestations with this worm do not develop

acutely and heavy infestations, when they occur, appear to develop over a long period of time. Infected sheep carry patent infection from one year to the next.

27.3.1.3.5

PATHOGENESIS

The relative pathogenicity of each lungworm is dependent on its predilection site. *D. filaria* lives in the trachea and bronchi so aspirated eggs, larvae, and debris can affect a large volume of lung tissue. It is therefore the most pathogenic species and provokes changes resembling those described for *D. viviparus*. The volume of damaged lung is however usually insufficient to cause severe dyspnea. Adult *P. rufescens* are found in smaller bronchioles and so associated lesions are much smaller. *M. capillaris* is found in the lung parenchyma where it becomes encysted in fibrous nodules. Lesions are thereby confined to its immediate surroundings. Consequently, this worm is generally considered to be relatively innocuous. Heavy mixed protostrongylid infections can impair pulmonary gaseous exchange.[3]

27.3.1.3.6

CLINICAL FINDINGS

Lambs 4–6 months of age are most severely affected with lungworms but sheep of all ages are susceptible. Clinically *D. filaria* is associated with bronchial irritation which results in coughing, moderate dyspnea and loss of condition. There may be added fever and evidence of toxemia if secondary bacterial infection occurs. It is highly pathogenic in young goats. *P. rufescens* infestations in sheep and goats cause clinical signs similar to those of *D. filaria*.

27.3.1.3.7

CLINICAL PATHOLOGY

Laboratory diagnosis depends upon the detection of first-stage larvae in the feces by the Baermann technique. *D. filaria* larvae have refractile granules in their intestinal cells and a conical tail. *P. rufescens* has a wavy tail as does *M. capillaris* which, in addition, has a spine just anterior to the tail.

27.3.1.3.8

NECROPSY FINDINGS

D. filaria lesions are similar to those of the subacute form of parasitic bronchitis in calves with exudate in the bronchioles and scattered patches of consolidation, but widespread lesions are not common. *M. capillaris* is found in small fibrous nodules up to 5 mm in diameter. Most of these are in the parenchyma of the lung immediately under

the pleura. Many of them are calcified and often contain only one live or dead worm. Infestation of goats leads to a diffuse infection quite different to the nodular reaction in sheep and to the production of an interstitial pneumonia.[4] Whether this is due solely to *M. capillaris* infection or whether a chlamydial or viral agent is involved has not been determined.

27.3.1.3.9

DIAGNOSTIC CONFIRMATION

The presence of larvae in the feces confirms lungworm infection but their number is often no indication of the degree of infestation.

27.3.1.3.9.1

DIFFERENTIAL DIAGNOSIS

Lungworm infestation in sheep needs to be differentiated from maedi and jaagsiekte.

27.3.1.3.10

TREATMENT

Ivermectin, moxidectin, the benzimidazoles and levamisole are effective against *D. filaria* at normal dose rates. Ivermectin, in addition, has a label claim for *P. rufescens*. It is doubtful whether treatment of sheep for *M. capillaris* is ever justified. In goats, one or two doses of ivermectin (0.2 mg/kg) or elevated doses of benzimidazoles destroys the adult worms but not the immature stage,[5,6] but regular doses of fenbendazole (up to 5.0 mg/kg/d) in the feed for 1–2 weeks or albendazole (1.0 mg/kg for 2 weeks) are highly effective against all stages.[6]

27.3.1.3.11

CONTROL

An attenuated vaccine for *D. filaria* is available in a few countries where this worm is a particular problem. With most forms of sheep husbandry, there are few precautionary measures that can be taken, particularly against lungworms with molluscan intermediate hosts.

27.3.1.4

LUNGWORM IN PIGS

27.3.1.4.1

ETIOLOGY

The lungworms which infest pigs are *Metastrongylus apri* (*M. elongatus*), *M. salmi*, and *M. pudendotectus*. *M. apri* is the most common species but mixed infestations are not uncommon.

27.3.1.4.2

LIFECYCLE

Adult *Metastrongylus* spp. appear much like *D. viviparus* in the bronchi of their host. Their lifecycles are also similar except that *Metastrongylus* spp. eggs are passed in the feces and earthworms act as intermediate hosts. Here development to infective larvae takes about 2 weeks and transmission occurs when the earthworm is eaten by a pig.

27.3.1.4.2.1

Synopsis

27.3.1.4.2.1.1

Etiology

The nematode parasites *Metastrongylus apri* (*M. elongatus*), *M. salmi*, and *M. pudendotectus*.

27.3.1.4.2.1.2

Epidemiology

Transmission is by ingestion of the earthworm intermediate host.

27.3.1.4.2.1.3

Signs

Check in growth rate; barking cough.

27.3.1.4.2.1.4

Clinical pathology

Characteristic eggs in feces.

27.3.1.4.2.1.5

Lesions

Grayish nodules near the ventral border of the diaphragmatic lobes of the lung.

27.3.1.4.2.1.6

Diagnostic confirmation

Characteristic eggs in feces.

27.3.1.4.2.1.7

Treatment

Doramectin, ivermectin, fenbendazole, flubendazole, levamisole.

27.3.1.4.2.1.8

Control

Difficult, unless pigs reared on concrete.

27.3.1.4.3

EPIDEMIOLOGY

The disease is most prevalent in pigs 4–6 months of age in husbandry systems that allow access to earthworms. The eggs first appear in the feces 3–4 weeks after infestation and at their peak reach levels of 25–50 epg. The eggs are very resistant to cold temperatures and can survive for over 1 year in the soil. Larvae may survive in the earthworm for up to 7 years. The primary host must ingest an intermediate host to become infested and this is an important factor influencing the spread of the disease. Once ingested the infective larvae migrate to the lungs in much the same manner as do *D. viviparus* larvae. Many infestations are asymptomatic and induce immunity against re-infection.

27.3.1.4.4

PATHOGENESIS

The pathogenesis is similar to that of *D. viviparus*. These worms may provide a route of transmission for swine influenza virus, and possibly hog cholera virus, from pig to pig, but this is unproven.

27.3.1.4.5

CLINICAL FINDINGS

Lungworm infection in pigs can cause a marked check in growth rate. The bronchitis is accompanied by sporadic bouts of a barking cough, which is easily stimulated by exercise. Pneumonia is a feature of severe cases.

27.3.1.4.6

CLINICAL PATHOLOGY

Laboratory diagnosis is by demonstration of the characteristic eggs in feces.

1569

1570

27.3.1.4.7

NECROPSY FINDINGS

Early lesions comprise small areas of consolidation due to verminous pneumonia. More chronic cases have bronchitis, emphysema, peribronchial lymphoid hyperplasia and bronchiolar muscular hypertrophy, often accompanied by areas of overinflation. The lesions are small and discrete, appearing as grayish nodules up to 1 cm in diameter and are present particularly at the ventral border of the diaphragmatic lobes.[1]

27.3.1.4.8

DIAGNOSTIC CONFIRMATION

The *Metastrongylus* egg is embryonated (larvated), has a thick shell and a wavy outline. They may be missed on routine screening as they are usually passed in small numbers and do not float well in saturated salt (NaCl) solution. A flotation fluid with a higher specific gravity should be used. There will always be a history of access to yards or paddocks where earthworms exist.

27.3.1.4.9

TREATMENT

A number of anthelmintics are effective at normal pig dose rates including doramectin, ivermectin, fenbendazole, and flubendazole. Levamisole (8 mg/kg) has been used in the water or feed.

27.3.1.4.9.1

DIFFERENTIAL DIAGNOSIS

- Other swine pneumonias
- Migrating larvae in heavy *Ascaris* infestation.

27.3.1.4.10

CONTROL

Rearing pigs on concrete reduces the risk considerably but, in view of the longevity of the eggs and larvae in the earthworm, little can be done if pigs are kept on contaminated land. Pastures which are known to be contaminated should be left for at least 6 months before restocking, although infested earthworms may persist in hog lots for up to 4 years.

27.3.2 Kidney worm disease in pigs

27.3.2.1 ETIOLOGY

Stephanurosis is a disease of swine caused by the migration of larvae and young adults of the nematode para-site *Stephanurus dentatus* through the body.

27.3.2.1.1 Synopsis

27.3.2.1.1.1 Etiology

The nematode parasite *Stephanurus dentatus*.

27.3.2.1.1.2 Epidemiology

Eggs are shed in urine; infective larvae enter pig when swallowed or by skin penetration; earthworms can act as transport hosts; prepatent period at least 6 months.

27.3.2.1.1.3 Signs

Poor growth; emaciation in severe cases with stiffness of gait.

27.3.2.1.1.4 Clinical pathology

Eggs in urine; eosinophilia.

27.3.2.1.1.5 Lesions

Fibrosis and abscess formation in perirenal tissues; fibrotic scarring of liver; lesions may occur in other organs.

27.3.2.1.1.6

Diagnostic confirmation

Eggs in urine; characteristic necropsy appearance.

27.3.2.1.1.7

Treatment

Adults and larvae: fenbendazole, ivermectin, doramectin; *adults only*: levamisole.

27.3.2.1.1.8

Control

Regular anthelmintic treatments at 4-month intervals; breeding only from gilts; keeping paddocks bare and dry.

27.3.2.2

LIFECYCLE

S. dentatus are large (2–5 cm) thick roundworms which inhabit the perirenal tissues, and less commonly the other abdominal organs and spinal canal of the pig. Adult worms lie in cysts around the renal pelvis and the wall of the ureter. The cysts communicate with the urinary passages and the eggs are passed out into the urine of the host. They are very prolific egg layers and an infective adult sow may void as many as a million eggs in a day. Under suitable environmental conditions the eggs hatch and, after undergoing two molts, the larvae develop to the infective third stage in about 4 d. The eggs and larvae are very sensitive to cold and desiccation; eggs in a dry situation die within an hour. Exposure to temperatures below 10°C (50°F) is damaging and 4°C (40°F) is lethal. Most larvae in optimum conditions of moisture, warmth, and shelter from sunlight survive for about 3 months, some for as long as 5 months. Larvae may survive for long periods as facultative parasites in earthworms and this may enable the larvae to survive even when the soil microclimate is adverse.

Larvae may penetrate the skin or be ingested. Larvae that are ingested cross the wall of the stomach, or more commonly the small intestine, and reach the liver via the portal vessels; from the skin the larvae reach the systemic circulation and pass to the liver via the lungs in 1–6 weeks.[1] In the liver the larvae migrate from the blood vessels through the parenchyma and eventually, about 3 months after infestation, having undergone a fourth molt, penetrate the capsule of the liver and reach the perirenal tissues to establish themselves as adults. Egg laying usually commences about 6 months after infestation but the prepatent period may be very much longer and individual worms appear to live as long as 2 years.[2]

During their migration the larvae often follow an erratic path and cause the development of atypical lesions and clinical signs. These larvae often reach maturity in these aberrant sites and prenatal infection can occur in this way.[3]

27.3.2.3

EPIDEMIOLOGY

Kidney worms occur commonly in most tropical and subtropical countries such as Africa, the East and West Indies, Brazil, Hawaii, Philippines, the southern United States, and Australia, where the climate is sufficiently mild to permit the survival of eggs and larvae.

27.3.2.4

PATHOGENESIS

The principal effect of these worms is the damage caused by the migrating larvae and young adults. The migrating worms cause a great deal of necrosis, fibrosis, and occasional abscess formation along the path of their migration and this is most marked in the perirenal tissues and the liver. *S. dentatus* have been observed rarely in cattle. Experimentally dosed calves develop severe hepatic injury similar to that which occurs in pigs but the lifecycle is not completed and no perirenal lesions develop.

27.3.2.5

CLINICAL FINDINGS

The mortality rate is not high; production losses and condemnation of parts or all of the infested carcass are of greatest economic significance. Poor growth in spite of a good appetite may be the only sign in mild cases.[4] Badly affected animals become emaciated and develop ascites. In the early stages, nodules in the skin of the belly wall and enlargement and soreness of the peripheral lymph nodes may be evident.[3] Many apparently unrelated clinical signs are produced by aberrant larvae. For example, thrombi may be induced in blood vessels such as the portal veins, hepatic artery and posterior vena cava, while paralysis may result if larvae invade the spinal cord. Involvement of the psoas muscles, causes local pain and stiffness of gait. The passage of larvae through the peritoneum and pleura gives rise to adhesions. Larvae may also become encysted in the lung. Weakness and eventual paralysis of the hindlegs occur in a number of cases. Passage through the peritoneum and pleura causes the formation of adhesions and many larvae become encysted in the lung.

27.3.2.6

CLINICAL PATHOLOGY

Large, thin-walled, embryonated eggs are present in the urine when adult worms are present in the ureter wall. An eosinophilia is seen 2–3 weeks after infection, peaking at 6–7 weeks and still elevated at 20 weeks.[5] However, this has little specific diagnostic significance. Anemia does not occur. Only a transient rise in aspartate aminotransferase is seen and serum enzymes seem to be of little value in diagnosis.[5]

27.3.2.7

NECROPSY FINDINGS

The common findings include[1]: fibrosis and abscess formation in perirenal tissues with large adult worms present here and occasionally in the pelvis of the kidney and ureter,[2] infarcts and scars in the kidney and enlargement and scarring of the liver, sometimes accompanied by ascites. The hepatic lesions include irregular whitish tracks in the parenchyma, extensive fibrosis, hemorrhage and eosinophilic abscess formation. The liver may be covered with a diphtheritic membrane. Larvae may also be present in peripheral lymph nodes and cutaneous nodules, in small abscesses in the lung and pancreas and in thrombi of blood vessels, particularly in the liver and lungs. Pleurisy and peritonitis if they are present are usually manifested by adhesions.

27.3.2.8

DIAGNOSTIC CONFIRMATION

A definite diagnosis of stephanurosis may be made by finding eggs in the urine or by necropsy. Young pigs with a heavy infestation of larvae may present a problem in diagnosis because adult worms and characteristic renal lesions may not yet be present. An ELISA test can detect infection from 2 weeks after infection,[6] but serological tests are not likely to become a routine diagnostic procedure.

27.3.2.8.1

DIFFERENTIAL DIAGNOSIS

- Other causes of poor growth and emaciation in pigs, e.g. poor nutrition and chronic bacterial diseases such as necrotic enteritis and swine dysentery, but these are accompanied by intermittent diarrhea
- Other parasitic diseases such as ascariosis and hyostrongylosis

- Other causes of posterior weakness in pigs such as vitamin A deficiency, osteodystrophia, sometimes fracture of a lumbar vertebra, brucellosis, erysipelas when intervertebral joints are involved, or by spinal cord abscess or lymphoma.

27.3.2.9

TREATMENT

Single doses of ivermectin or doramectin at 0.3 mg/kg, or fenbendazole at 3 mg/kg in the feed for 3 d are effective against migrating and adult stages,[7,8] while levamisole at 8 mg/kg removes the adults only but thereby prevents egg output for at least 4 weeks.[9]

27.3.2.10

CONTROL

Regular anthelmintic treatment of all pigs with fenbendazole or ivermectin at 4-month intervals should prevent further contamination of the environment with eggs. The free-living stages should then eventually die out, but this may take some time as infected earthworms may survive for at least 1 year.

Management techniques may also be used for controlling kidney worm. As the prepatent period of *S. dentatus* is at least 6 months, one method is to breed entirely from gilts until the transmission cycle is broken.[10] Under this system the gilts are raised, allowed to farrow and sent to market as soon as the litter is weaned and before any eggs are shed. Boars are confined on concrete to prevent contamination of the soil by eggs in their urine. This technique has the advantage of maintaining a fully stocked farm while control is being achieved but has obvious economic penalties.

Other management techniques depend on the provision of dry ground where eggs and larvae are less likely to survive. Sleeping shelters should be placed on high ground, preferably bare of vegetation. Because pigs in yards commonly urinate against fences, a 2–3 m strip of earth inside the boundary should be kept free of herbage. Muddy spots and water holes should be filled in and drainage provided. Water and feed troughs should be on a concrete apron. Young animals should be segregated from adults and fields rested for 3–6 months after the adults are removed. Such programs are rewarding if carried out diligently and intelligently, but the extra work involved has militated against general acceptance of this approach. Because of the importance of mature animals as sources of infestation, early replacement of breeding stock is recommended in problem herds.

27.4 Nematode induced skin conditions

27.4.1 SUMMER SORES IN HORSES

27.4.1.1 Synopsis

27.4.1.1.1 Etiology

Three nematode species, *Habronema muscae*, *H. majus* (syn. *H. microstoma*), and *Draschia megastoma* infect the horse.

27.4.1.1.2 Epidemiology

Larvae from eggs in the feces are ingested by fly larvae; adult flies deposit infective larvae on skin.

27.4.1.1.3

Signs

Larvae deposited in wounds or in eye cause local inflammation and the development of extensive granulation tissue.

27.4.1.1.4

Clinical pathology

Larvae may be found in skin scrapings, biopsies or discharges; marked local eosinophilia.

27.4.1.1.5

Lesions

Adult *D. megastoma* cause tumorlike lesions in stomach; other species cause a catarrhal enteritis.

27.4.1.1.6

Diagnostic confirmation

Gastric form: eggs difficult to find in feces; *Cutaneous form*: demonstration of larvae, eosinophils in biopsy or scraping.

27.4.1.1.7

Treatment

Ivermectin.

27.4.1.1.8

Control

Protect horses from flies; treat all skin wounds promptly.

27.4.1.2

ETIOLOGY

The various forms of cutaneous habronemosis, with local names such as ‘summer sores', ‘swamp cancer', and ‘bursattee', involve three nematode species, *Habronema muscae*, *H. majus* (syn. *microstoma*), and *Draschia megastoma*, the adults of which infest the stomach of horses.

27.4.1.3

LIFECYCLE

Habronema spp. adults are larger (1–2.5 cm long) than those of *D. megastoma* (1.25 cm). The lifecycles are indirect; all species use flies as their intermediate hosts. *H. muscae* and *D. megastoma* mainly use the house fly (*Musca domestica*) but can use other muscid

species, while *H. majus* usually passes through the stable fly (*Stomoxys calcitrans*), although *Haematobia irritans exigua*, *Sarcophaga melanura*, and the house fly can also be used. The thin-walled larvated eggs hatch in the manure and are ingested by maggots in which they develop. The infective form is reached about the time the adult fly emerges from the puparium. Horses become infected by swallowing dead flies with feed or water or, alternatively, infective larvae may pass through the proboscis of the fly when it is feeding on the lips or on wounds. Larvae that are swallowed reach maturity in the stomach while those deposited in wounds cause cutaneous habronemosis. Stray larvae may be found anywhere throughout the body but occasionally massive invasion of the lungs is seen.[1]

1571

1572

27.4.1.4

EPIDEMIOLOGY

Habronema and *Draschia* have a worldwide distribution. They are of importance only in warmer climates, where they are commonly found, especially in wetter areas where the intermediate hosts are common. Elsewhere they tend to be a sporadic nuisance. Gastric granulomas and most cutaneous lesions appear to be associated with *D. megastoma*, although typical cutaneous lesions do occur naturally and have been produced experimentally by the cutaneous implantation of *H. majus* or *H. muscae* larvae. The latter however only cause a transitory reaction. Horses of all ages are susceptible but the disease is most common in adults.

27.4.1.5

PATHOGENESIS

Two types of gastric habronemosis occur. The more serious is associated with *D. megastoma*. Larvae invade the gastric mucosa and cause the development of large granulomatous masses which later fibrose. These tumors contain adult worms and have a central orifice through which eggs and larvae escape into the lumen. In many horses, the lesions cause only a mild chronic gastritis. In rare cases perforation occurs and is followed by a local peritonitis, which may involve the intestine causing constriction or the spleen causing abscesses. *H. majus* and *H. muscae* do not cause tumors but penetrate the stomach glands and cause a catarrhal gastritis with the production of a thick tenacious mucus. Heavy burdens may cause ulceration.

In cutaneous and conjunctival habronemosis, *Habronema* spp. larvae deposited in wounds cause local inflammation and the development of extensive granulation tissue. Secondary bacterial or mycotic invasions may occur. In the eye, similar lesions form on

the inner canthus, the nictitating membrane or the eyelid. These can cause profuse lacrimation and other signs of local irritation.

27.4.1.6

CLINICAL FINDINGS

Gastric habronemosis does not usually provoke clinical signs, but affected animals may, on occasion, have a poor coat and a variable appetite. Large tumors may cause pyloric obstruction and gastric distension. When perforation occurs there is depression, a fever of 39.5–40.5°C (103–105°F) and pain and heat on the left side just behind the costal arch. Mild-to-moderate colic may be evidenced when intestinal stenosis is present. If the spleen is involved there is marked anemia and a gross increase in the total leukocyte count with a shift to the left.

Cutaneous habronemosis is manifested by the appearance of lesions on those parts of the body where skin wounds or excoriations are most likely to occur and where the horse cannot easily displace the vector flies. Thus they are most common on the face below the medial canthus of the eye and on the midline of the abdomen, extending in males onto the prepuce and penis. Less commonly, lesions may be found on the legs and withers but those occurring in the region of the fetlocks and coronary band are especially serious. The cutaneous lesions commence as small papules with eroded, scab-covered centers. Development is rapid and individual lesions may increase to 30 cm in diameter in a few months. The center is depressed and composed of coarse, red granulation tissue covered with a grayish necrotic membrane and the edges are raised and thickened. Although the lesions do not usually heal spontaneously, they may regress in colder weather and recur the following summer. There is little discharge. The sores are unsightly, inconvenient and cause some irritation.

In conjunctival habronemosis lesions on the nictitating membrane may be as large as 5 mm in diameter. The conjunctivitis is manifested by small, yellow, necrotic masses about 1 mm in diameter,[2] accompanied by soreness and lacrimation, which do not respond to standard treatments for bacterial conjunctivitis.

27.4.1.7

CLINICAL PATHOLOGY

Diagnosis is difficult in the gastric form of the disease because the eggs and larvae are not easy to find in the feces. Biopsy of a cutaneous lesion reveals connective tissue containing small, yellow caseous areas up to 5 mm in diameter. Larvae may be found in skin

scrapings or biopsies and ocular lesions can be found in the conjunctival sac or discharges. A marked local eosinophilia occurs.[3]

27.4.1.8

NECROPSY FINDINGS

Tumor-like lesions of *D. megastoma* bulge into the lumen of the stomach and may reach the size of a golf ball. Adult *Habronema* are stout worms but their presence is often masked by a thick tenacious layer of mucus. This is on the glandular part of the stomach and often close to the margo plicatus.

Granulomatous lesions may be found in all the sites mentioned in the description of clinical signs, and although varying in size are of essentially the same composition as described under biopsy earlier. Horses which have had the cutaneous form of the disease may have small nodules in the parenchyma of the lung. These are hard, yellowish and contain inspissated pus and larvae.

27.4.1.9

DIAGNOSTIC CONFIRMATION

A biopsy will confirm clinical diagnosis of the cutaneous and conjunctival forms of the condition. Molecular techniques are being developed for detection and specific identification of parasite DNA in feces and biopsies.[4]

27.4.1.9.1

DIFFERENTIAL DIAGNOSIS

The gastric form of habronemosis is difficult to differentiate from infestation with stomach bot (*Gasterophilus*) larvae or *Trichostrongylus axei*. These parasites often co-exist in the same animal. Cutaneous habronemosis must be distinguished from:

- Fungal granulomata associated with *Hyphomyces destruens*
- Overgrowth of granulation tissue following a wound
- Equine sarcoids.

27.4.1.10

TREATMENT

Few anthelmintics have been adequately tested against *Habronema* spp. and *D. megastoma*. Ivermectin 0.2 mg/kg will remove these species from the stomach with a single treatment[5] but a second dose is sometimes necessary to promote healing in

cutaneous lesions.[6] Moxidectin (0.4) is active against adult *Habronema muscae*.[7] Fenbendazole used at 10 mg/kg for 5 d is reported to have high efficiency against *D. megastoma* and possibly *Habronema* spp.[8]

27.4.1.11 CONTROL

Interruption of the lifecycle by careful disposal of horse manure and control of the fly population are obvious measures. In enzootic areas all skin wounds and excoriations should be treated promptly to promote healing and protect them against flies.

27.4.2 RHABDITID DERMATITIS

Pelodera is a sub-genus of the soil nematode *Rhabditis*. Dermatitis associated with the larvae of *P. strongyloides* is rare. It is recorded most commonly in the dog but outbreaks have been observed in cattle, sheep and horses.[1–3] It has also been an incidental finding in other skin diseases associated with poor husbandry practices.[4] Alopecia is marked, particularly on the neck and flanks. In moderate cases the skin on affected areas is thickened, wrinkled and scurfy and some pustules are present on the ventral abdomen and udder.[5] Pustules are up to 1 cm in diameter and contain thick, yellow caseous material and worms. There is marked irritation and, in severe cases, affected areas are swollen, raw and exude serum.

1572 1573

Pelodera strongyloides is a free-living soil nematode found particularly in decaying leaf mould and similar material. When warm blooded animals lie on its habitat for prolonged periods it takes the opportunity to invade the skin. Thus, infestation is encouraged by

housing animals on warm, wet bedding. Under favorable conditions the disease may spread rapidly.[3] In these circumstances the lesions occur most commonly where the skin contacts the bedding. The nematodes are easily detected in skin scrapings or biopsy specimens, and in samples of the bedding, preferably taken from the top few centimeters in the pen.

Control measures include the regular removal of soiled bedding and steps to ensure that the litter is kept dry. Spontaneous recovery usually occurs if these precautions are taken but local application of a parasiticide and symptomatic therapy will speed recovery.

27.4.3

ONCHOCERCOSIS

Onchocerca spp. are filamentous, thread-like nematodes found mostly as convoluted masses in fibrous tissues. They vary in length; those of the horse are 15–18 cm long, while bovine species may be as long as 75 cm. They are filarial worms and the females produce motile embryos (microfilariae). These congregate in the skin and subcutaneous tissues at the favored feeding site of their intermediate host. Each *Onchocerca* species uses a particular biting fly, usually a species of *Culicoides* (midge) or *Simulium* (blackfly). Transmission takes place when infective larvae that develop in the fly are deposited on the skin of their host at a subsequent feed.

Infestation by adult worms is often symptomless and prevalence tends to increase with age. Relatively non-pathogenic species of widespread occurrence in cattle include *O. gutturosa* in the ligamentum nuchae and *O. lienalis* in the gastrosplenic ligament, while horses often harbor *O. cervicalis* in the ligamentum nuchae and *O. reticulata* around the flexor tendons. Some cause rejection of meat for human consumption. *O. gibsoni* in Australian cattle, for example, provokes nodules up to 3 cm across in subcutaneous tissues, especially in the brisket. *O. ochengi* produces subcutaneous nodules in African cattle, most commonly on the

scrotum and udder. Other species may be more pathogenic such as *O. armillata*, which lives in the aorta of cattle, buffalo and goats in India and Iran.[1]

Losses caused by adult worms are slight although *O. gibsoni* in cattle causes unsightly lesions and rejection of beef carcasses from the high-class meat trade. The characteristic nodules of *O. gibsoni* are usually freely movable and consist of fibrous tissue canalized by the long body of the worms. With *O. armillata*, the inner wall of the aorta may be corrugated and swollen. In horses, new infections with *O. reticulata* may cause swelling of the suspensory ligament and a hot edematous swelling of the posterior part of the cannon which persists for 3–4 weeks. After the swelling subsides, the suspensory ligament remains thickened and small caseated or calcified nodules may be palpated. Affected animals are lame while the area is edematous and swollen, but many recover when the swelling disappears. *O. cervicalis* causes fibrotic, caseous and calcified lesions in the ligamentum nuchae but clinical signs are not seen. The conditions known as ‘poll evil' and ‘fistulous withers' are no longer thought to be associated with this parasite.

Microfilariae may sometimes be damaging. Those of *O. cervicalis*, for example, are occasionally observed in the cornea of horses but the proposed causal relationship with periodic ophthalmitis is no longer thought to be valid. They can however induce hypersensitivity reactions in the skin of some individuals. Lesions are characterized by alopecia, scaliness and pruritus, particularly along the ventral abdomen. They may extend between the forelegs and backlegs to include the thigh, and in severe cases they may extend up the lower abdominal wall. Some horses have lesions on the face, neck, or thorax.[2] The lesions may be confused with those associated with hornfly feeding but these are more likely to include crusting and ulcerating dermatitis.[3] In onchocercosis, microfilariae are not detectable in the bloodstream but may be found in skin biopsies. *O. ochengi* in African cattle has been associated with a dermatitis resembling demodectic mange and pox,[4] while in Turkey microfilariae of *O. gutterosa*, *O. lienalis*, and an unidentified species have recently been reported in association with teat lesions including sores, chaps, and nodules.[5]

Control of the intermediate hosts is virtually impossible but valuable horses prone to hypersensitivity to *O. cervicalis* microfilariae can be partially protected by housing at night as most *Culicoides* species feed during twilight hours and/or at night. The use of insect repellents and avoidance, if possible, of grazing areas where the insects are likely to be in large numbers will also be beneficial. There is no specific treatment for the adult worms. A novel approach has been the experimental use of tetracycline to eliminate *O. ochengi* by killing the symbiotic bacterium *Wolbachia* which is found in many, but not all, filarial

species.[6] Ivermectin 0.2 mg/kg[2,7] or moxidectin 0.4 mg/kg[8] can be used to eliminate microfilariae in horses. About 10% of treated horses develop an edematous reaction within 24 h.[2] This is usually restricted to the area of the lesion but some may develop a pruritic ventral edema.

27.4.4

ELAEOPHOROSIS (FILARIAL DERMATITIS) IN SHEEP

Elaeophora spp. are filarial nematodes that inhabit blood vessels. Relatively non-pathogenic species include *E. bohmi*, which has been reported in horses in Austria and *E. poeli*, which occurs in cattle in Africa and Asia. Of greater clinical significance is *E. schneideri*, which is primarily a parasite of mule deer in North America. Elk, white-tailed deer, and moose may act as reservoir hosts.[1] This species causes chronic disease in adult sheep grazing at high altitudes during the summer months. Horse flies such as *Hybomitra* and *Tabanus* spp. are intermediate hosts.[2] In sheep, larvae develop in the leptomeningeal arteries for 4–5 weeks after which they migrate into the common carotid and internal maxillary arteries, although they may also be found in other arteries. The adults grow to 120 mm in length and mature in about 5 months.[3]

Elaeophorosis usually produces no detectable effects in the natural host, the mule deer. Clinical signs in abnormal hosts attributable to migrating worms are thought to be the result

of the prolonged sojourn of the larvae in smaller blood vessels. This reduces blood flow and may result in blindness, deafness, and circling. 1573 1574 It also means that the larvae are larger when they pass through the cerebral retina to get to the common carotid and rupture of a rete artery, hemorrhage and death may follow. Further signs are caused by the microfilariae. Sheep usually show a severe dermatitis on the poll, forehead, face, feet, and ventral abdomen. Initially the lesions are small and circumscribed but the irritation produced by them is so intense that scratching causes extensive areas of bleeding, with a granular surface containing numerous small abscesses. On the feet, the lesions extend from the coronary band to above the fetlock and cause much local swelling. Recurrent periods of quiescence occur and scabs form over the lesions, but 2–3 d later, scratching recommences and the lesions are spread further. The course is long, often 7 months and up to 3 years, but recovery may eventually occur. Residual lesions include deformity of the hooves and bare, thickened patches of skin. Lesions also occur in the nasal and oral mucosae and on the cornea. Abnormalities of the eye include cataract, iridocyclitis and corneal opacity. While sight often remains adequate in sheep, it is usually lost in elk.

27.4.4.1

DIFFERENTIAL DIAGNOSIS

The distribution of lesions and pruritus help to distinguish elaeophorosis from:

- contagious ecthyma
- mycotic dermatitis
- strawberry foot rot.

Photosensitization lesions may have a very similar distribution and appearance to those caused by the elaeophorid filaria but there is usually marked edema and swelling and a history of access to photosensitizing or hepatotoxic plants.

Microfilariae may be detected in skin biopsies but skin scrapings and blood examinations are not satisfactory. The number of microfilariae in the skin of sheep is always low and negative results may be obtained in known positive sheep.

Treatment with piperazine (220 mg/kg) has been suggested. Unfortunately the death of adult parasites in heavily infected sheep may cause the death of the host, presumably by blocking branches of the carotid arteries. Information is lacking on the activity of modern drugs on this infection.

27.4.5 PARAFILARIOSIS

Horses in Europe, particularly eastern Europe, China, South America, and North Africa, are sometimes infected with *Parafilaria multipapillosa*, a 3–6 cm long nematode. The female lives in a nodule in the skin which it pierces to lay eggs on the surface. The subcutaneous nodules ulcerate, bleed, heal, and disappear spontaneously. The hemorrhagic exudate from the lesion attracts bloodsucking flies such as *Haematobia*, which ingest the eggs and act as the intermediate host. The condition is relatively benign, occurring in the spring, summer, and autumn. Many nodules may occur on a horse but although unsightly they do little harm unless they interfere with harness straps.

Similar lesions in cattle are associated with *P. bovicola*, which is endemic in eastern and some western European countries, India, the Philippines, Japan, and South Africa. It has recently become established in Canada, Ireland, and Sweden, where it spread at a rate of 50 km/year.[1,2] Muscid flies, for example *Musca autumnalis* in Sweden, act as the intermediate host[3] and the prepatent period in cattle is 7–10 months. The condition is seen mostly in late winter, spring, and summer and causes widespread economic losses due to carcass trimming and hide damage. The majority of lesions are superficial and localized but sometimes they cover the whole carcass. In such cases intermuscular lesions will be found within the fascia of adjacent muscles. Subperitoneal, abdominal, subpleural, and thoracic lesions may also occur and cause condemnation of the whole carcass. *Suifilaria suis* causes similar lesions in the pig in South Africa.

Clinical signs are restricted to the presence of bleeding points and a diagnosis may be made by examining a smear of the exudate microscopically for larvated eggs. Ivermectin markedly

reduces the area of the lesions and the mass of affected tissue.[4] A control program for *P. bovicola* using ivermectin has been evaluated.[5] Blood spots were dramatically reduced but transmission was not stopped. Nitroxynil 20 mg/kg twice at 72-hour intervals is effective in reducing the number and area of lesions but care must be taken to ensure accuracy of dosing or toxic signs of drug overdose may be seen.[6] Topical levamisole may also be effective.[2]

27.4.6

STEPHANOFILARIOSIS

Stephanofilaria spp. are very small (up to 8 mm) filarial nematodes living in cysts at the base of hair follicles. They are associated with subcutaneous tissue lesions in cattle and buffalo. There are a number of species including *S. dedoesi* (synonyms *S. assamensis*, *S. kaeli*, and *S. okinawaensis*), which provokes a dermatitis (‘cascado') affecting the eyes, neck, withers, shoulders and dewlap in parts of Asia as well as ‘humpsore' in India, leg sores on cattle in Malaysia and muzzle and teat lesions in Japan. *S. zaheeri* causes ‘earsore' in India and *S. stilesi* is responsible for dermatitis of the ventral abdomen in parts of the United States and Russia. A similar species in Queensland, Australia affects the head, neck, dewlap, and sternum. *S. boomkeri* has recently been described in pigs in Africa.[1] The adult worms release microfilariae which later develop in flies that feed on the sores. The vector for *S. dedoesi* is *Musca conducens*, while the horn fly *Haematobia irritans* is intermediate host for *S. stilesi* in the United States. The Australian species is probably spread by the buffalo fly, *Haematobia irritans exigua*.[2]

Cutaneous stephanofilariosis starts with small papules which later coalesce to produce lesions varying from 3 to 15 cm in diameter. They are an extreme irritant and evidence of rubbing is present. Part but not all of the hair is lost and dried exudate forms a thick, crumbly scab which may crack to expose blood-stained fluid. Skin scrapings taken from beneath the

scab may reveal worm fragments. If healing occurs, the scab disappears leaving a scar. Infection does not affect growth rate, and treatment and control is required only in stud cattle where lesions are esthetically undesirable. Ivermectin is an effective microfilaricide in buffaloes and reduces the number of adult worms.[3] Oral levamisole 7.5 mg/kg once or twice at 3 to 4-week intervals is reported to be effective.[4] Ointments containing insecticides may aid control. The Asian species require a pre-existing wound for infection to take place. Simple wound prevention and treatment would therefore reduce the risk of disease in this region.

27.5 Nematodes affecting eyes or nervous system

27.5.1 *THELAZIA* (EYEWORM)

A number of species of the nematode genus *Thelazia* occur in the conjunctival sac and tear ducts of mammals throughout the world. *T. gulosa* and *T. skrjabini* are the main species in cattle in the New World while *T. rhodesi* is the commonest in the Old World and *T. lacrymalis* is cosmopolitan in horses. They are thin worms up to 2 cm long. Infestation is often inapparent but they may cause excessive lacrimation, photophobia, conjunctivitis, keratitis, corneal ulceration, and abscess formation on the eyelids.[1–3] In horses, this condition mainly occurs in young animals. One survey in Kentucky, in the United States, found 43% of horses up to 4 years old to be infected.[4] In those species that have been studied, the lifecycles are indirect with muscid flies, particularly the face fly *Musca autumnalis*,[5] being the intermediate hosts. These flies deposit larvae on the conjunctiva when feeding on fluid around the eye. The disease is mainly seen in summer and autumn when the

flies are active. It is usually more common in cattle than horses[3] and worms may be more abundant in beef than in dairy cattle.[6] Eyeworm in cattle is differentiated from infectious keratitis by observing the adult worm in the conjunctival sac or demonstrating first-stage larvae in eye washings. Ivermectin and doramectin are active against the adult worm in cattle[7,8] but anecdotal reports suggest that it may be less effective in horses.

27.5.2 *HALICEPHALOBUS*

Halicephalobus gingivalis (*H. delatrix; Micronema delatrix*) is a small nematode which has been found in horses on rare occasions. Like *Pelodera*, it is a free-living saprophytic organism that has the ability to become an opportunistic parasite. *H. gingivalis* however invades the deeper tissues where it reproduces. Enormous numbers may be seen in granulomatous lesions that grow to several cm in diameter. Lesions may be found near the eye, in the prepuce, nares or the maxilla. The latter may be sufficiently large to cause the hard palate to bulge, displacing the molars and causing difficulty in mastication.[1] Putative hematogenous spread gives rise to similar lesions in the kidney which may be misdiagnosed as renal neoplasia. The worm also invades the brain and spinal cord[2] but here the lesions are usually microscopic and consist of discrete granulomata with a vascular orientation. Affected horses may show a wide variety of clinical signs including lethargy, ataxia, and

incoordination leading to recumbency and death.[3] Diagnosis of superficial lesions is by demonstration of worms and larvae in biopsy samples, but more often *H. gingivalis* infection is identified retrospectively in histological sections following necropsy.[4] The worms are 250–430 μm long, have a characteristic bilobed pharynx and often contain a single large egg. This infection must be considered in the differential diagnosis of equine cerebrospinal nematodosis.[3,4] Treatment with ivermectin at the maximum safe dose has been attempted although the susceptibility of the worm to this compound is uncertain.

27.5.3 *ELAPHOSTRONGYLUS*

Cerebrospinal elaphostrongylosis (CSE) or neurofilariosis is a disease of sheep, goats, and camelids caused by infestation of the brain and spinal cord with the nematode *Elaphostrongylus* and related genera. This genus is closely related to the lungworms of small ruminants but is found in the cranial subarachnoid space, cranial venous sinuses and occasionally in the spinal subarachnoid space. *Parelaphostrongylus tenuis* occurs in white-tailed deer in eastern North America and parts of western Canada, *E. cervi* in deer in Europe and New Zealand, and *E. rangiferi* in reindeer in Scandinavia. Eggs or larvae are carried to the lungs, undergo a tracheal migration and the first-stage larvae are passed in the feces. The larvae are quite resistant to adverse environmental conditions and enter slugs or snails to develop into infective larvae. The lifecycle is complete when infected molluscs are ingested by deer and the larvae penetrate the abomasum, migrate, possibly along spinal nerves, to the spinal cord where they develop into adults and migrate into the subarachnoid space.[1]

Clinical signs are not seen in infected deer, but in sheep and goats the worm continually moves through nervous system tissue causing limping and incoordination followed by almost complete paralysis of the hindlimbs or of the neck, body, and all four legs.[1–3] There are no signs of cerebral involvement and affected animals remain bright and continue to eat. If given supportive treatment they may survive for at least 1 month. *P. tenuis* also transmits to moose and is responsible for the nervous signs in ‘moose sickness', including[4]:

- Weakness
- Incoordination
- Circling
- Impaired vision
- Blindness
- Abnormal carriage of the head
- Paralysis
- Lack of fear of man
- Aggressiveness.

No reliable treatment is available for CSE. Ivermectin has no effect on the adult worms, possibly because the large molecules of this compound cannot pass the blood–brain barrier.[5] One clinical report describes the treatment of 17 light to moderately affected goats with an NSAID (flunixin meglumine) together with ivermectin and fenbendazole for 5 days.[6] Complete recovery occurred in three, partial recovery in eight, but euthanasia was necessary for the remainder.

27.5.4

SETARIA

Setaria spp. are long (5–10 cm) thread-like filarial nematodes commonly found in the peritoneal cavity of most domestic animals. *S. labiato-papillosa* is a cosmopolitan parasite of cattle while *S. digitata* and the closely related, and perhaps synonymous, species *S. marshalli* occur only in Asia. *S. equina* is found worldwide in horses. Adult females produce motile embryos (microfilariae) which circulate in the peripheral blood of the infected animal and are taken up by mosquitoes.[1] Infective larvae develop in the intermediate host and are released when the mosquito subsequently feeds. *S. labiato-papillosa* reaches maturity in cattle in 8–10 months. Despite their size, the presence of these worms in the abdominal cavity causes no significant clinical effect.

1575 1576

Serious disease may result if *S. labiato-papillosa* or *S. digitata* infect animals other than their own natural host, especially horses, sheep, goats, and humans. In these hosts, they migrate in an abnormal manner causing epizootic cerebrospinal nematodosis (with local names including Lumbar Paralysis and Kumri) when they invade the brain and spinal cord. Juvenile *S. digitata* may also invade the eye. Although *Setaria* is found in cattle in many countries, cerebrospinal nematodosis is largely restricted to Israel, Japan, China, Korea, India, and Sri Lanka. The incidence is increasing in Taiwan[1] and a single case has been reported from the United States.[2] Ocular filariosis is seen most commonly in Japan. These are diseases of the summer and autumn when the vectors are most prevalent. The cerebrospinal form sometimes occurs in epidemic proportions, causing deaths in horses, sheep, and goats.

Cerebrospinal nematodiosis may be rapid in onset with affected animals dying within a few days or it may occur gradually over a few days. There may be acute or subacute paresis with weakness and incoordination or paralysis involving the hindlegs most commonly, but sometimes all four legs. Recovery is only partial in many animals but others show only a mild neurological disorder, which gradually becomes indiscernible. There are no systemic

signs and the animals may continue to eat. Other diseases causing similar clinical signs include enzootic equine ataxia in horses and paralytic rabies in sheep and goats as lesions due to traumatic injury, spinal cord abscess, warble fly larvae, *Strongylus vulgaris*, or *Halicephalobus gingivalis*.

At necropsy, there are no macroscopic changes and sections need to be taken from many levels of the spinal cord to find histological lesions. Focal areas of malacia or microcavitation are seen and in adjacent sites there may be loss of myelin, axonal swelling, degeneration and gitter cell formation.[2] Migratory pathways are indicated by necrotic tracts. Where nervous signs have been present for only a few days, a worm or worm fragments may occasionally be found. Molecular techniques have been developed for identifying the responsible species.[3]

Anthelmintics will not resolve existing lesions but may prevent further damage. Little has been published on treatment or control. Ivermectin gave moderate efficacy (80–88%) against adult *S. equina* in ponies.[4] In a field study, none of 221 goats and sheep injected twice with ivermectin at a dose of 0.2 mg/kg developed setariosis, while 17 of 303 non-injected animals suffered from the disease.[5]

27.6 Diseases associated with trematodes and cestodes

27.6.1 Hepatic diseases associated with trematodes

27.6.1.1 FASCIOLOSIS (LIVER FLUKE DISEASE)

27.6.1.1.1 Synopsis

27.6.1.1.1.1 Etiology

Fasciola hepatica and, in warmer climates, *F. gigantica*.

27.6.1.1.1.2 Epidemiology

Infection by ingestion of metacercariae on herbage; geographical distribution, seasonality and disease risk determined by occurrence of intermediate hosts (lymnaeid mud snails).

27.6.1.1.1.3 Signs

Acute syndrome (*sheep*): sudden death; *chronic syndrome* (*sheep and cattle*): weight loss, reduced milk yield, pallor, submandibular edema.

27.6.1.1.1.4 Clinical pathology

Acute syndrome: raised serum glutamate dehydrogenase concentrations, anemia; *chronic syndrome*: characteristic eggs in feces, anemia, hypoalbuminemia, raised serum gamma-glutamyl transpeptidase concentrations.

27.6.1.1.1.5 Lesions

Acute syndrome: pale friable liver with parasitic tracts and hemorrhage; *chronic syndrome*: fibrous liver, bile ducts grossly distended and thickened.

27.6.1.1.1.6 Diagnostic confirmation

Acute syndrome: immature flukes in liver parenchyma at necropsy: *chronic syndrome*: characteristic eggs in feces, immunoassay of blood or milk.

27.6.1.1.7

Treatment

Albendazole, clorsulon, closantel, netobimin, nitroxynil, oxyclozanide, triclabendazole; not all are equally effective against all stages of fluke development.

27.6.1.1.8

Control

Avoidance or drainage of snail habitats; strategic anthelmintic dosing programs.

27.6.1.1.2

ETIOLOGY

Fasciola hepatica is the most common and important liver fluke and has a cosmopolitan distribution in cooler climates. Lymnaeid mud snails are intermediate hosts and release the infective form, the metacercaria, onto herbage. Hepatic fasciolosis is mainly of economic importance in sheep or cattle but other species may provide a reservoir of infection. *F. hepatica* may infest all domestic animals, including Equidae[1] and many wildlife species, but chronically infected sheep are the most important source of pasture contamination.[2] Human cases are usually associated with the ingestion of marsh plants such as watercress. A similar but larger fluke, *F. gigantica*, is restricted to warmer regions including parts of Africa and Asia.

27.6.1.1.3

LIFECYCLE

Adult *Fasciola* live in bile ducts producing eggs that are excreted with the feces. Hatching occurs in moist conditions only after the first larval stage, the miracidium, has formed and when ambient temperatures rise above 5–6°C (41–43°F). Miracidia must find and invade the tissues of a suitable host snail within 24–30 h. After several cycles of asexual multiplication, the flukes leave the snail as cercariae. These attach to herbage and transform into metacercariae by secreting a tough protective cyst wall. After ingestion by the final host, each metacercaria releases an immature fluke which crosses the intestinal wall and migrates across the peritoneal cavity to the liver. The migration is sometimes misdirected and ectopic flukes can be found in the lungs, particularly in cattle. The young *F. hepatica* migrate through the hepatic parenchyma for about 4–5 weeks, growing from 0.1 to 10 mm. After entering the bile ducts, they more than double in size before egg laying starts about 10–12 weeks after infestation. Adult sheep and cattle may remain carriers for many years because of the longevity of the adult flukes.

27.6.1.1.4

EPIDEMIOLOGY

The risk of hepatic fasciolosis is determined by the numbers of infected lymnaeid snails in the grazing area. The disease has a predictable seasonal pattern in regions where snails 1576
are active for only part of the year. Some lymnaeid snails have a more aquatic habit than 1577
others but all are restricted to damp or wet environments. In general, they prefer non-acidic low-lying swampy areas with slowly moving water, but land with small streams, springs, blocked drainage or spillages from, for example, water troughs may also be potentially hazardous for grazing stock. Land frequently irrigated is also highly suitable for infection to take place. Snails burrow into the soil to survive dry periods and release cercariae when free water is present. Snail habitats may be permanent or temporary. The latter expand and contract depending on water availability. Construction works, such as road building may alter drainage patterns and disease risk. Improvement of peaty pastures by lime application may increase risk by reducing soil acidity and allowing snail colonization.

Important host snails for *F. hepatica* include *Lymnaea truncatula* in the United Kingdom and Europe and *Galba bulimoides*, *G. B. techella* and others in the United States. *L. columella* has been identified as an intermediate host in Canada and more recently in Brazil. In New Zealand, *L. tomentosa* and *L. truncatula* have occurred without fasciolosis becoming a major problem but the introduction of *L. columella* markedly increased the range and severity of the disease.[3] *L. tomentosa* is the major host snail in Australia, although *L. columella* has been reported to be present in non-farming areas and *L. viridis* has also been found.

The main factors determining the timing and severity of hepatic fasciolosis are those that influence the number of metacercariae accumulating on herbage. In particular, temperature and rainfall affect both the spatial and temporal abundance of snail hosts and the rate of development of fluke eggs and larvae.[4] Temperatures above 10°C (50°F) are necessary before the snail hosts will breed or before *F. hepatica* can develop within the snail. No development therefore takes place during the winter in most countries.

The 'summer infection of the snail' by miracidia hatching from eggs in spring and early summer results in the emergence of cercariae and the consequent contamination of herbage some 5–8 weeks later.[5] For any climatic region, cercarial shedding is a fairly regular occurrence with minor differences in timing determined by year-to-year variations in weather patterns.

The 'winter infection of the snail' is a separate cycle occurring when snails are exposed to miracidia in the autumn. Fluke development ceases in the snail during winter but resumes as temperatures rise the following spring. The relative importance of this cycle depends on the mortality rate of the snails during the winter,[6] which varies from region to region and from year to year.

The availability of metacercariae is generally greatest in the late summer and autumn. Massive numbers can accumulate in wetter parts of the British Isles and Europe.[7] Metacercariae may overwinter in milder climates to infect stock in spring, but they do not survive under severe winter conditions. In hot, dry regions, metacercariae die quickly and so in Australia, for example, infections are usually due to a recent release of cercariae.[8] Stock are also vulnerable in dry conditions if forced to feed in swampy areas to obtain green feed. Metacercariae are normally killed during the preparation of hay or silage, but can remain infective for up to 8 months if hay is harvested in moist conditions and not properly dried.

The clinical outcome of infection depends largely on the density of metacercariae on the herbage. This will be greatest when weather conditions have been favorable for snail reproduction and survival. A high intake of metacercariae over a short time will produce acute disease; lower numbers over a longer period lead to chronic disease. The degree to which immunity influences the course of infection differs with species. Sheep and goats do not develop a strong protective immune response to *F. hepatica* and remain vulnerable throughout their lives. Cattle eventually expel most but not all of their fluke burden and gain partial but not complete protection against reinfection.[9] *F. hepatica* has a number of survival mechanisms for evading host immune responses, including changing its surface antigen during migration,[10] releasing a proteolytic enzyme that can cleave immunoglobulins,[11] and modulating the host immune response.[12]

27.6.1.1.5

PATHOGENESIS

Acute hepatic fasciolosis is caused by the passage of young *F. hepatica* through the liver parenchyma. Clinical signs occur 5–6 weeks after the ingestion of large numbers of metacercariae. By this time, the migrating flukes are large enough to do substantial mechanical damage to the liver. Acute hepatic insufficiency and hemorrhage result.[13]

Quiescent spores of *Clostridium novyi* may become activated by the anaerobic necrotic conditions created in the liver parenchyma by migrating *F. hepatica*, causing infectious necrotic hepatitis (‘black disease') in sheep and cattle.[14] This migration has also been thought to stimulate the development of occasional cases of bacillary hemoglobinuria in cattle.

Chronic hepatic fasciolosis develops only after the adult flukes establish in the bile ducts. Here they cause cholangitis, biliary obstruction, fibrosis, and a leakage of plasma protein across the epithelium. Although this protein can be re-absorbed in the intestine, there is poor utilization and retention of nitrogen leading to hypoalbuminemia. There is also a loss of whole blood due to the feeding activities of the flukes. This exacerbates the hypoalbuminemia and eventually gives rise to anemia. It places a continuous drain on iron reserves[6] so that the anemia, which is initially normochromic, becomes hypochromic. These changes are more severe in sheep on a low plane of nutrition.[15] Chronic infection may limit growth rate and feed conversion in growing heifers and growth rate in beef cattle. *F. hepatica* infection has been reported to increase the susceptibility of cattle to *Salmonella dublin* and predispose to prolonged infection and fecal excretion.[16] Infected ewes may have reduced fertility, growth rate, and wool production.[17,18] Food intake is reduced and this leads to a reduction in efficiency of utilization of metabolizable energy and a reduction in calcium and protein deposition in the carcass.[19]

The fibrotic response of the liver to fluke-induced damage varies with the host and may partially account for differing species susceptibilities.[13] The severe reaction in cattle, which includes calcification of the bile ducts, appears to hinder the establishment and feeding of challenge infections thereby reinforcing immune responses.[7] Both horses and pigs are generally highly resistant to infection with *F. hepatica* but differ in their mode of resistance. Horses overcome the migrating fluke at an early stage so that few reach the liver, while in the pig the resistance mechanism operates in the liver parenchyma.[20]

27.6.1.1.6

CLINICAL FINDINGS

27.6.1.1.6.1

Acute fasciolosis

Acute fasciolosis in sheep most often occurs as sudden death without other apparent clinical abnormality. It is usually seen in the summer and autumn but may occur at any

time when sheep have the opportunity to graze heavily contaminated herbage. If the disease is observed clinically in sheep it is manifested by:

- Dullness
- Weakness
- Lack of appetite
- Pallor and edema of mucosae and conjunctivae
- Pain when pressure is exerted over the area of the liver. Death occurs quickly and may be accompanied by the passage of blood-stained discharges from the nostrils and anus. Outbreaks are usually of relatively short duration; most deaths occur within a period of 2–3 weeks. Acute fasciolosis rarely occurs in cattle.

1577
1578

27.6.1.1.6.2

Subacute fasciolosis

Acute and chronic fasciolosis are opposite ends of the clinical spectrum. Intermediate forms occur and a subacute syndrome has been described in sheep. The major clinical signs are weight loss and pallor of the mucous membranes. Submandibular edema will be seen in only a few cases, but many animals will resent palpation over the region of the liver.

27.6.1.1.6.3

Chronic fasciolosis

Chronic fasciolosis does not become apparent until several weeks after the danger of acute disease has receded. Affected sheep lose weight, develop submandibular edema (bottle jaw), and pallor of the mucosae over a period of weeks. Shedding of the wool may occur. The course of the disease is often as long as 2–3 months in those which die; many survive but may remain in poor condition for longer periods. Cattle also lose weight, especially if lactating, milk production falls and anemia may develop.

27.6.1.1.7

CLINICAL PATHOLOGY

In acute fasciolosis there is a severe normochromic anemia, eosinophilia, and a severe hypoalbuminemia. Blood concentrations of a number of serum enzymes indicating liver damage are elevated. Glutamate dehydrogenase is of particular value when the young flukes are migrating through the liver parenchyma but concentrations fall after they enter

the bile ducts.[21] Increases in aspartate aminotransferase can be measured from 4 weeks and are useful as a measure of immature infection.[22] Eggs will not be present in the feces as the flukes are still juvenile.

In subacute and chronic disease weight loss is associated with a severe hypochromic, macrocytic anemia, hypoalbuminemia and hyperglobulinemia. Submandibular edema and ascites occur only occasionally in the subacute condition but more frequently in the chronic disease.[6] Serum gamma-glutamyl transpeptidase concentrations are raised by the activities of adult *F. hepatica* in the bile ducts.[23] Other liver function tests are not significantly affected. A diagnosis of chronic hepatic fasciolosis can be confirmed by the detection of large numbers of characteristic, operculated fluke eggs in the feces. These eggs are thin-walled and stained yellow-brown by biliary pigments. They are dense and do not rise satisfactorily in all flotation solutions. Zinc sulfate solution (specific gravity 1.36) is recommended. Sedimentation tests are more accurate.[24] Operculated fluke eggs are also characteristic of paramphistome infections and care is needed to differentiate the two.

27.6.1.1.8

NECROPSY FINDINGS

27.6.1.1.8.1

Acute hepatic fasciolosis

Acute hepatic fasciolosis is characterized by a badly damaged, swollen liver. The peritoneal cavity may contain an excess of blood-stained serum. The liver capsule has many small perforations and subcapsular hemorrhages. The parenchyma shows tracts of damaged tissue and is more friable than normal. The immature flukes are often so small that they are not readily discernible. They are most easily demonstrated by slicing a piece of liver thinly and shaking in water, permitting the flukes to settle to the bottom. The size of the flukes may allow estimation of the duration of the infection and this may help to determine which pastures are hazardous.

27.6.1.1.8.2

Chronic hepatic fasciolosis

Leaf-like flukes, measuring some 3.5 ×1 cm, are present in grossly enlarged and thickened bile ducts, particularly in the ventral lobe of the liver. The bile ducts may protrude above the surface of the liver and cysts may be present due to blockage of ducts with flukes and desquamated epithelial cells. Calcification of the bile duct walls is a common finding in cattle but not in sheep. The hepatic parenchyma is extensively

fibrosed and the hepatic lymph nodes are dark brown in color. Anemia, edema, and emaciation are attendant abnormalities.

27.6.1.1.9

DIAGNOSTIC CONFIRMATION

In fluke endemic areas, fasciolosis must be considered as a possible factor in any outbreak of chronic ill health in sheep, either as the main cause or as a contributory factor along with other debilitating disease processes. To support a diagnosis, account should be taken of grazing history and the seasonality of fasciolosis in that locality. There should be fluke eggs in the feces and characteristic hepatic lesions at necropsy. As these may be ubiquitous findings in endemic areas, a judgment is necessary to determine whether the severity of the lesions is sufficient to incriminate the fluke as the sole or major contributing etiological factor. Enzyme-linked immunoassays (ELISA) are available for use with blood or milk and are particularly useful for the diagnosis of infection in cattle on an individual or herd basis. A rise in antibody can be detected by 2 weeks after infection and keeps rising until week 6.[25] Coproantigen tests are being developed.

Acute disease can only be confirmed at necropsy.

27.6.1.1.9.1

DIFFERENTIAL DIAGNOSIS

Acute fasciolosis

- Hemonchosis
- Infectious necrotic hepatiti
- Eperythrozoonosis
- Anthrax
- Enterotoxemia.

Chronic fasciolosis

- Nutritional deficiencies of copper or cobalt
- Other internal parasitisms, including parasitic gastroenteritis (particularly hemonchosis) in sheep and ostertagiosis in cattle

- Johne's disease

27.6.1.1.10

TREATMENT

Not all compounds are equally effective against all stages of development of *F. hepatica* in the body. At the time of writing triclabendazole comes closest to this ideal. For treatment of acute fasciolosis, it is essential to choose a product highly effective against the juveniles that damage the liver parenchyma. For chronic disease, a compound active against the adult fluke is required. Product safety is an important consideration as hepatic detoxicating mechanisms are already impaired. Flukicides can be used therapeutically for treating disease or prophylactically to prevent outbreaks. Some bind to plasma proteins (e.g. closantel) or erythrocytes (clorsulon), thereby extending their period of protection. All flukicides either have milk-withholding periods or are prohibited from use in animals providing milk for human consumption and so the best time to treat dairy cattle is at the drying off stage. Many products combine a flukicide with a nematocide, but these should only be used when there is simultaneous risk from the two types of parasite.

Triclabendazole is a compound specifically for use against *F. hepatica* in sheep (10 mg/kg) and cattle (12 mg/kg). Higher doses are required for the control of *F. gigantica* in buffalo.[26] It is highly effective against all stages of fluke from 2 days old in sheep and 2 weeks in cattle[27] and is the drug of choice in outbreaks of acute fluke disease. An 8 to 10-week dosing interval is recommended for use in control programs. Fluke populations resistant to triclabendazole have developed following intensive control regimens.[28] Triclabendazole has been used with success in horses and donkeys (12 mg/kg) but is not licensed for this purpose.[29,30]

1578

1579

Albendazole is a broad-spectrum compound also active against nematodes and cestodes. It is effective against adult *F. hepatica* at a dose-rate of 7.5 mg/kg in sheep and 10 mg/kg in cattle. It is ovicidal and will kill any *F. hepatica* eggs present in bile ducts or the alimentary tract at the time of treatment. Netobimin (20 mg/kg) is metabolized to albendazole in the body and has similar activity against *F. hepatica*.

Closantel will kill the majority of flukes older than 4 weeks in sheep at a dose rate of 10 mg/kg and will delay fluke egg output by animals grazing contaminated pasture for up to 12 weeks. It also has a residual effect against *H. contortus*.

Clorsulon is supplied in combination with ivermectin for combined fluke and roundworm control in cattle. At the recommended dose rate of 2 mg/kg by SC injection, clorsulon is effective against adult and 12 to 14-week immature flukes but activity against 8-week-old *F. hepatica* is variable.

Nitroxynil is given subcutaneously at 10 mg/kg and has good efficiency against the adult fluke but the dose has to be increased by up to 50% to obtain adequate control of acute disease. In sheep, spillage stains the fleece yellow. It cannot be given orally as the rumen microflora reduce the compound to an inactive metabolite.

Oxyclozanide used in cattle (10 mg/kg) has a shorter milk withholding period than most other flukicides. It has a significant effect against adult fluke but is inactive against immature forms. It may cause transient softening of feces. This compound has been combined with levamisole to provide activity against fluke and gastrointestinal nematodes.

27.6.1.1.11

CONTROL

Preventive measures are required in endemic areas as fasciolosis can cause death without warning or significant production losses. An integrated strategic approach is more cost beneficial than reliance on routine dosing and is less likely to induce anthelmintic resistance, but requires detailed knowledge of the local epidemiological cycle. In some countries where risk varies from year to year, predictions of likely disease levels are issued based on analysis of meteorological data and field observations. This enables control measures to be intensified when necessary. Computer models have been devised to assist this process.[31]

Segregation of stock from sources of infection is the ideal method of control but not always feasible in practice. Identification and mapping of snail habitats may enable grazing plans to be devised that avoid danger areas at times of high risk. Where habitats are restricted in size and clearly defined, it may be possible to exclude stock by fencing.

Stock on heavily contaminated land may be protected from acute fasciolosis by taking advantage of the interval between the ingestion of metacercariae and the onset of disease. Treatment during this period with a product effective against young flukes will eliminate the migrating parasites before they cause serious liver damage. A further dose may be necessary depending on the duration of metacercarial intake and residual activity of the chosen product. Some metacercariae will continue to be ingested after the main

danger period has passed and so treatment with a product active against adult *F. hepatica* will be needed some weeks later to insure against possible losses from chronic fasciolosis. Additional strategic doses may be required in regions where the winter infection of the snail is of significance. The precise timing of each of these doses depends on the local epidemiological pattern.

Reduction of pasture contamination with metacercariae will reduce future risk. This can be done by preventing the snails from becoming infected with *F. hepatica* or by diminishing the size of the snail population. To achieve the first objective, adult flukes should be eliminated from the bile ducts of all grazing stock in spring and early summer. This prevents egg excretion and minimizes the numbers of snail-seeking miracidia at this crucial stage in the epidemiological cycle.[32] There may however be wildlife sources of *F. hepatica* eggs which cannot be controlled in this way. Snail numbers can be reduced by restricting the size of their habitat. This can be done, where feasible, by draining boggy areas and by making sure that ditches, land drains, water troughs etc. are well maintained.

With stall-fed buffaloes in the tropics advantage can be taken of the fact that the metacercariae of *F. gigantica* concentrate on the lower part of forage plants, for example rice straw. This can be cut off and used for other purposes while the upper, uninfected, part is fed to the farm stock.[33]

Chemical snail control was widely practised before reliable animal treatments became available. Lymnaeid snails have enormous reproductive capacity and can quickly recolonize wet land. Application therefore has to be very thorough to have a significant season-long effect and there must be no possibility of invasion from neighboring land. Chemicals can be applied in spring for maximum impact on the snail population before breeding starts, or later in the season when snails are plentiful but before cercariae start to emerge. Efficacy is reduced if luxuriant plant growth hinders penetration to soil level. Inorganic compounds such as copper sulfate or sodium pentachlorophenate are effective but may be potentially hazardous to humans, stock, and the environment. Safer and more selective low-volume molluscicides such as *n*-trityl morpholine[34] have been developed but are not commercially available at the time of writing.

Vaccines for *F. hepatica* are under development. One of these which uses recombinant fluke cathepsin L proteinases has given up to 79% protection against infection in cattle

and sheep.[35] Successful vaccination strategies elicit Th1 rather than the Th2 immune responses induced by natural infection.

27.6.1.2

FASCIOLOIDES

Fascioloides magna is a large liver fluke found mainly in North America but it also occurs in some European countries. It is a parasite of moose and deer but it can also infect other animals grazing the same pastures. Sheep and goats are particularly susceptible to infection. The prevalence of infestation in cattle may be high in endemic areas but they are seldom affected clinically.

The lifecycle in normal hosts is similar to that of *Fasciola hepatica* except that it grows up to 10 cm long and 3 cm broad in thin-walled cysts in the liver parenchyma. Connections between the cysts and the bile ducts allow the passage of eggs with the feces. Lymnaeid snails act as intermediate hosts and the final host is infected by ingesting metacercariae encysted on herbage. The fluke enters the liver after spending 3–4 weeks in the peritoneal cavity.

In sheep and goats the fluke continually migrates, never becoming encapsulated but forming large, black tracts. Hepatic damage and hemorrhage are so severe that one or two flukes can be fatal. In cattle, necrotic tracts are seen in the parenchyma as well as dark, thick-walled cysts 4 cm in diameter. These have no connection to the bile ducts. Clinical signs in sheep and goats are similar to acute hepatic fasciolosis and infected animals can die without warning. Infestations in cattle are usually inapparent but may cause signs similar to chronic hepatic fasciolosis. Eggs may be found in the feces. These resemble *F. hepatica* eggs but are larger and have a small appendage at the blunter end.

Most anthelmintics effective against *F. hepatica* are also active against *F. magna* but few confirmatory reports have been published. Albendazole 10 mg/kg removed 74% of *F. magna* in naturally infected cattle,[2] closantel 15 mg/kg had good efficacy in sheep 8 weeks after infection,[3] clorsuron gave variable results in cattle at 21 mg/kg,[4] while triclabendazole 20 mg/kg was 99% effective in sheep when given 12 weeks postinfection.[5]

27.6.1.3

DICROCOELIUM

Dicrocoelium dendriticum is a small trematode widespread in Europe and Asia but with restricted distribution in North America and the British Isles. Its lifecycle differs from that of *Fasciola hepatica* in several ways. Eggs passed in the feces are eaten by land snails such as *Helicella* spp. and *Cochlicopa lubrica*. Cercariae are passed in slime balls used as food by ants of the genus *Formica*. Grazing animals become infected when they swallow ants containing metacercariae. The flukes travel up the common bile duct to settle in bile ducts within the liver. In contrast to *F. hepatica*, the intermediate hosts of *D. dendriticum* are not associated with wet habitats. Transmission can therefore occur on well drained farmland and even dry heathland pastures. Protective immunity is poor and heavy infections (tens of thousands) can accumulate.

Pathogenicity is low as *D. dendriticum* does not migrate across the liver parenchyma. Very heavy infections may cause ill-thrift. Lesions comprise fibrosis of the parenchyma and a proliferation and thickening of smaller bile ducts.[1] Infectious necrotic hepatitis may develop as a result of infestation. At necropsy, *D. dendriticum* infection can be recognized as the flukes are smaller (0.5–1.5 cm) than *F. hepatica*, are lanceolate in shape and confined to the bile ducts. Eggs in feces are small, operculate, asymmetrical and dark brown in color. They are dense structures and flotation fluids with a high specific gravity, such as potassium iodomercurate solution (SG 1.44), are recommended.[2]

Treatment with albendazole at 15 mg/kg is effective[3] as is netobimin at 20 mg/kg.[4]

27.6.2 Stomach fluke disease (Intestinal amphistomosis)

27.6.2.1 Synopsis

27.6.2.1.1 Etiology

Paramphistomum cervi, P. microbothrioides and related flukes.

27.6.2.1.2 Epidemiology

Infection by ingestion of metacercariae on herbage; geographical distribution, seasonality, and disease risk determined by occurrence of intermediate hosts (aquatic planorbid snails).

27.6.2.1.3 Signs

Severe enteritis, fetid diarrhea.

27.6.2.1.4 Clinical pathology

Hypoalbuminemia; immature flukes may be passed in feces.

27.6.2.1.5 Lesions

Duodenal mucosa thickened, mucus blood stained with large numbers of small, flesh-colored flukes.

27.6.2.1.6 Diagnostic confirmation

Demonstration of immature flukes in feces.

27.6.2.1.7 Treatment

Oxyclozanide.

27.6.2.1.8 Control

Avoidance or drainage of snail habitats; anthelmintic treatments to prevent contamination of pastures with eggs.

27.6.2.2

ETIOLOGY

Intestinal amphistomosis is associated with paramphistome flukes in the duodenum migrating towards the fore-stomachs. Cattle and, to a lesser extent, sheep are at risk of infection. The paramphistomes are cosmopolitan but disease is most common in warmer regions, particularly Australasia, Africa, and India. Commonly recorded paramphistome species include *Paramphistomum cervi*, *P. microbothrioides*, *P. liorchis*, *P. ichikawai*, *P. microbothrium*, *Calicophoron calicophorum*, *Ceylonocotyle streptocoelium*, *Calicophoron ijimai*, and *Cotylophoron cotylophoron*.

27.6.2.3

LIFECYCLE

The lifecycle is similar to that of *Fasciola hepatica* except that the intermediate hosts are planorbid snails and the immature flukes migrate proximally along the duodenum and through the abomasum to reach their predilection site in the rumen and reticulum. The period required for maturation varies from 6 weeks to 4 months.

27.6.2.4

EPIDEMIOLOGY

Planorbid snails are aquatic. They are more adaptable and occupy more diverse habitats than lymnaeid snails. Thus zones of endemicity for intestinal amphistomosis and hepatic fasciolosis do not necessarily coincide. Most outbreaks of disease occur during the late summer, autumn, and early winter when pastures are heavily contaminated with encysted cercariae. Planorbid snails multiply very rapidly in warm, watery environments but can subsequently survive dry conditions. Metacercariae are therefore found on pastures prone to flooding as well as on herbage in and around ponds, streams and other water sources.[1] All ages of cattle, sheep, goats, and wild ruminants grazing near water or on land liable to flooding may be affected but young cattle in the yearling class are the usual subjects. It is possible that some degree of immunity develops.

1580 1581

27.6.2.5

PATHOGENESIS

The immature flukes excyst in the duodenum or mid-to-proximal jejunum. As they migrate they attach firmly to the mucosa and may penetrate as far as the muscularis mucosa. Damage is related to the numbers of migrating flukes and increases in intensity from localized enteritis through patches of villous atrophy to severe destruction of the mucosa.[2] Clinical and production effects are dependent upon the extent of the lesions as some

compensation for functional deficiency can take place in the undamaged lower small intestine. The presence of mature flukes in the rumen does not usually elicit any significant response but in massive infections papillae are short and red, becoming fused into aggregations with ruminal contents adhering firmly to the surface.[2]

27.6.2.6

CLINICAL FINDINGS

Severe enteritis associated with enormous numbers of migrating flukes in the duodenum seems to be the only manifestation of disease. A characteristic and persistent fetid diarrhea is accompanied by weakness, depression, dehydration and anorexia. There may also be submaxillary edema and obvious pallor of the mucosae. Death usually occurs 15–20 d after the first signs appear. The mortality rate in heavily infested animals may be high. Mature flukes in the forestomachs of animals normally cause little harm, although loss of weight, anemia, a rough dry coat, and a drop in production have been ascribed to heavy infestations.[3]

27.6.2.7

CLINICAL PATHOLOGY

A sedimentation and decanting technique may be used to find immature flukes passed in feces. The larvae are round with prominent anterior and posterior suckers. Because the disease is caused by immature forms, eggs are not usually present in the feces, although they may be detectable in older animals in the same herd. Paramphistome eggs are dense structures and so sedimentation methods for detection are preferred to flotation.[4] The eggs have a distinct operculum and resemble those of *F. hepatica*, but the shell is colorless. Blood biochemistry reveals a marked drop in total plasma protein, due largely to a fall in plasma albumin.[5]

27.6.2.8

NECROPSY FINDINGS

There is muscular atrophy, subcutaneous edema and accumulations of fluid in the body cavities, and the fat deposits are gelatinous. In the upper part of the duodenum the mucosa is thickened, covered with blood-stained mucus and there are patches of hemorrhage under the serosa. Large numbers of small, flesh-colored flukes (3–4 mm long and 1–2 mm wide) are present in this area but decrease in number towards the ileum. There may be none in the abomasum and forestomachs. There may be a few in the peritoneal cavity and on histological examination the young flukes are present not only on the mucosal surface but are also embedded in the mucosa and deeper layers.[5]

27.6.2.9

DIAGNOSTIC CONFIRMATION

The occurrence in yearling cattle of a severe enteritis, unaccompanied by fever, in environmental conditions suitable for the propagation of flukes and where host snails can be found should arouse suspicion of intestinal amphistomosis. Confirmation depends on demonstration of immature flukes in feces or at necropsy. Care is needed as the small parasites are easily missed.

27.6.2.9.1

DIFFERENTIAL DIAGNOSIS

- Nutritional deficiency of copper
- Infestation intestinal roundworms
- Infectious enteritides, but these are usually accompanied by fever
- Johne's disease in adult animals, but this is a much more chronic disease
- Poisonings, including many weeds, inorganic arsenic and lead.

27.6.2.10

TREATMENT

Few drugs are highly effective.[6] Two doses of oxyclozanide 18.7 mg/kg 2 days apart, or a single dose of hexachlorophene 20 mg/kg, give consistent results against immature paramphistomes in cattle, but hexachlorophene may show toxicity at this dose rate.[7] Niclosamide 160 mg/kg as a single dose or as two doses 3 d apart is effective but somewhat variable[7]; however, it has good activity at 100 mg/kg against immature paramphistomes in sheep.[8] Bithionol has been used in Asia and Africa.

27.6.2.11

CONTROL

Animals should, where possible, be denied access to contaminated areas. Otherwise, regular treatments will be needed. Snails quickly repopulate pastures once they become wet and stock should be removed before the intermediate hosts start to shed large numbers of cercariae (1–2 months from infection of the snail depending on temperature). Metacercariae may persist on pasture for up to 2 or 3 months after flood water has dried out.

In areas where paramphistomes are a regular problem, knowledge of the local epidemiological cycle will help determine optimum times for prophylactic treatments. These are aimed at killing migrating immature flukes before they cause disease and at reducing egg-output by adult worms, thereby minimizing opportunity for snails to become infected. Drainage of low-lying areas and destruction of host snails by the use of molluscicides could be considered.

27.6.3 Tapeworm infestations

27.6.3.1 ADULT TAPEWORM INFESTATION

27.6.3.1.1 Synopsis

27.6.3.1.1.1 Etiology

Cestodes belonging to the anoplocephalid family, including *Moniezia* spp. in ruminants and *Anoplocephala* spp. in horses.

27.6.3.1.1.2

Epidemiology

Transmission by ingestion of infected free-living pasture (oribatid) mites.

27.6.3.1.1.3

Signs

Little pathogenicity but heavy infestation may cause failure to thrive and, in horses, increased risk of ileocecal colic.

27.6.3.1.1.4

Clinical pathology

Demonstration of tapeworm eggs in feces.

27.6.3.1.1.5

Lesions

Horse: mild inflammation of intestinal mucosa with small ulcers.

27.6.3.1.1.6

Diagnostic confirmation

Tapeworm segments around tail base or on feces; eggs in feces.**Treatment** *Ruminants*: albendazole, febantel, fenbendazole, mebendazole, netobimin, oxfendazole, praziquantel. *Horses*: pyrantel, praziquantel.

27.6.3.1.1.7

Control

If necessary, periodic dosing is the only feasible option.

27.6.3.1.2

ETIOLOGY

The common anoplocephalid tapeworms of ruminants, *Moniezia expansa*, *M. benedeni*, and *Thysaniezia* (syn. *Helictometra giardi* also known as *T. ovilla*) are cosmopolitan, 1581
while *Avitellina* spp. occur mainly in Mediterranean countries and India, *Stilesia hepatica* in Africa and *Thysanosoma actinioides* in North America. 1582

In horses, *Anoplocephala magna*, *A. perfoliata*, and *Anoplocephaloides* (syn. *Paranoplocephala mamillana*) are cosmopolitan in their distribution.

27.6.3.1.3

LIFECYCLE

The lifecycles of all the anoplocephalid tapeworms are very similar. Eggs, which are immediately infective, pass in the feces of the host, either singly or protected within a tapeworm segment. These are ingested by free-living pasture (oribatid) mites and the intermediate stage (the metacestode) forms.[1] Mature tapeworms develop when the primary host accidentally swallows infected mites while grazing. Most species establish in the small intestine, but *T. actinioides* also invades biliary and pancreatic ducts, while *A. perfoliata* is found around the ileocecal junction and *S. hepatica* lives in the bile ducts. Lengths vary with species: *A. perfoliata* grows to 4–8 cm while *Moniezia* may be over 2 m.

27.6.3.1.4

EPIDEMIOLOGY

Oribatid mites are ubiquitous but most numerous on permanent pastures in the summer months. All grazing animals are therefore potentially at risk.

27.6.3.1.5

PATHOGENESIS

In ruminants, anoplocephalid tapeworms have little apparent effect on health.[2] In heavy infestations, it has been postulated that they may compete for nutrients, excrete toxic materials or, because of their length, interfere with the motility of the gut. Very heavy burdens of *M. expansa* in lambs have been associated with outbreaks of enterotoxemia.[3] Pancreatic and biliary duct species cause little harm but liver damage may cause rejection at meat inspection.

In horses, *A. perfoliata* causes a mild local inflammatory response around its site of attachment. Where 20 or more tapeworms are clustered, ulceration and other degenerative changes may occur. This may be accompanied by diphtheresis, granulomatosis and occasionally polyp formation.[4,5] The ileocecal valve may be thickened. Heavy infestations may interfere with gut motility and increase the risk of ileocecal colic. A recent matched case – control study indicated that 22% of a series of spasmodic colic cases were likely to have been tapeworm associated.[6] Evidence is accumulating to implicate *A. perfoliata* as a significant risk factor in ileal impaction cases.[6,7]

27.6.3.1.6

CLINICAL FINDINGS

In ruminants, there is disagreement over the importance of anoplocephalid tapeworms in causing disease; farmers usually overemphasize their importance while veterinarians underestimate it. Most infestations are asymptomatic but, on occasion, heavy burdens may result in unthriftiness, poor coat, vague digestive disturbances including constipation, mild diarrhea, and dysentery and sometimes anemia. These signs are restricted chiefly to animals less than 6 months of age on an inadequate diet. With *T. actinioides*, signs may be delayed until the animal reaches a later age. Infested animals may be more susceptible to the effects of other internal parasites and to other diseases or adverse environmental conditions.

Infections in horses are usually asymptomatic but, occasionally, heavy infestations may be associated with a range of abdominal conditions including colic, perforation of the cecum, ileocecal, cecocolic, and ileoileal intussusception, colonic, and cecal torsion, ileal thickening and obstruction.[8,9]

27.6.3.1.7

CLINICAL PATHOLOGY

Shed tapeworm segments may be visible macroscopically on the skin and hair around the tail base or in the feces. Eggs may be present in feces.

27.6.3.1.8

NECROPSY FINDINGS

The site of attachment on the intestinal mucosa may be indicated by the presence of a small ulcer and a mild inflammatory response. In the case of infestations with *T. actinioides* and *S. hepatica*, the presence of worms in the biliary and pancreatic ducts is accompanied by fibrosis and thickening of duct walls.

27.6.3.1.9

DIAGNOSTIC CONFIRMATION

Shed segments are much wider than they are long. They can be seen to be full of characteristic eggs if broken in a drop of water on a slide and examined microscopically. Anoplocephalid eggs are roughly D-shaped, thick-shelled, and contain an embryo within a chitinous ring. They are not easy to find in feces. Centrifugation/flotation using a saturated sugar solution is recommended for diagnosis in horses. At best the sensitivity of such techniques is only 60% for light infections rising to 90% for heavy burdens, and

so repeat samples may be needed to demonstrate the presence of the parasite.[10] Methods have been devised for detection of specific antibodies in serum[11] or antigen in feces[12] but are not as yet generally available.

27.6.3.1.9.1

DIFFERENTIAL DIAGNOSIS

- Other causes of unthriftiness
- In horses, other causes of colic.

27.6.3.1.10

TREATMENT

For ruminants, praziquantel 3.75 mg/kg is highly effective against *Moniezia* but higher doses are required for *Thysaniezia* spp. (5 mg/kg), *Avitellina* (7.5 mg/kg) and *Stilesia hepatica* (15 mg/kg). Some benzimidazole and pro-benzimidazole drugs have cestocidal activity in ruminants,[13] including albendazole, febantel, fenbendazole, mebendazole, netobimin, and oxfendazole. The efficacy of some of these compounds against *Moniezia* may be variable. Albendazole at 7.5 mg/kg is effective against cestodes in the bile ducts.[14]

For horses, pyrantel embonate at 38 mg/kg (i.e. double the standard dose for roundworm control) is an established treatment for *A. perfoliata* but is ineffective against *A. mammillana*. More recently praziquantel has been shown to provide high efficacy against *A. perfoliata* at doses of 1–2.5 mg/kg[15,16] and *A. mammillana*.[16,17] Such treatment may half the estimated risk of tapeworm associated colic.[18]

27.6.3.1.11

CONTROL

Control of the mites which act as intermediate hosts is impractical. If a potential problem is perceived in, for example, valuable horses, consideration could be given to reducing the numbers of oribatid mites by ploughing permanent pasture and reseeding. Otherwise stabling or tactical dosing, in early summer and autumn, are the only options.

27.6.4

LARVAL TAPEWORM INFESTATION

Livestock may act as the intermediate hosts for the tapeworms of humans and other animals. 1582
The larval tapeworms (metacestodes) develop as fluid-filled cysts, each at a typical site in the 1583
body. They act as space-occupying lesions and cause condemnation at meat inspection. Cattle around the world may harbor the metacestode of *Taenia saginata* (the beef tapeworm of humans), also known as *Cysticercus bovis*, in their striated musculature. *T. solium* (the pork tapeworm of humans) occurs similarly in pigs (known as *C. cellulosae*), mainly in

poorer regions.[1] The recently discovered *T. asiatica*, found only in East Asia, is closely related to *T. saginata* but uses pigs as its intermediate host.[2] Cysts in the musculature of sheep (known as *C. ovis*) are the intermediate form of a dog cestode (*T. ovis*). Hydatid cysts (*Echinococcus granulosus*), which develop in the lungs and/or liver of sheep, cattle and horses are also acquired from tapeworm eggs excreted by infected dogs and wild canids. These metacestodes rarely cause clinical disease in veterinary species (although some are serious zoonoses) and so the reader is referred to parasitology textbooks for detailed information.

Clinical disease is, however, associated with two other metacestodes. That of *Taenia* (*Multiceps*) *multiceps* causes coenurosis (‘gid') in sheep, which is described under diseases of the nervous system. *Taenia hydatigena* metacestodes are normally asymptomatic but if a sheep or goat swallows a whole tapeworm segment, which may contain 100 000 eggs, sudden death may occur as massive numbers of developing metacestodes (known as cysticerci) migrate through the liver parenchyma.[3,4] This condition (hepatitis cysticercosis) resembles acute hepatic fasciolosis but is an individual rather than a flock problem.

28 Chapter 28 Diseases associated with arthropod parasites

28.1 *GASTEROPHILUS* SPP. INFESTATION (STOMACH BOT)

Infestations with larvae of *Gasterophilus* spp. have a widespread distribution. They cause a chronic gastritis and a loss of condition in infested horses, donkeys, and mules. Reduced performance is often attributed to this infestation. On rare occasions they cause perforation of the stomach and death.

28.1.1 Synopsis

28.1.1.1 Etiology

Five species of *Gasterophilus* spp. which inhabit the gastrointestinal tract of horses.

28.1.1.2 Epidemiology

Eggs are laid on hair of the body or around the lips; eggs hatch spontaneously or are stimulated to hatch by oral grooming, larvae penetrate oral mucosa or external epithelium of cheek and migrate to inner regions of mouth, congregate at epithelial surface around teeth for 6–10 weeks before migration to the stomach and intestine. Larvae attach in stomach or intestine and remain there for some months before being passed in the feces. One species attaches near the rectum. Larvae pupate and adults emerge after 3–5 weeks. Adults only live a few days and are mainly active in the summer, the fly surviving as larvae in the stomach over the colder months.

28.1.1.3 Clinical signs

Adult flies frighten horses while larvae cause non-specific signs of unthriftiness.

28.1.1.4 Clinical pathology

Eggs can be seen on hairs on legs or around the lips by direct inspection.

28.1.1.5 Lesions

Area of larval attachment is pitted and the gastric wall may be thickened.

28.1.1.6

Diagnostic confirmation

Eggs present on hairs, characteristic lesions at autopsy.

28.1.1.7

Differential diagnosis

Unthriftiness usually associated with helminth infection.

28.1.1.8

Treatment

Ivermectin, trichlorphon, moxidectin.

28.1.1.9

Control

Treatment given when fly activity has ceased and when larvae are in stomach – usually two treatments in mid and late winter. Fringes and tassels protect against worry associated with one species of fly.

28.1.2

ETIOLOGY

Five species of flies of are known to parasitize domestic equids; *Gasterophilus nasalis, G. intestinalis, G. haemorrhoidalis, G. pecorum*, and *G. inermis*. Their larvae are the 'stomach bots' of horses, donkeys, and mules. Three species, *G. intestinalis, G. nasalis*, and *G. haemorrhoidalis*, are the most important and have a world wide distribution. The later larval stages inhabit the stomach and duodenum. These creamy pink larvae are thick, segmented, and about 5–15 mm long. The adult flies are golden brown, hairy, and about the size of a bee with two wings and vestigial mouth parts.

28.1.3

LIFE CYCLE AND EPIDEMIOLOGY

Flies do not feed and only live a few days.[1] They are active during the summer months and there may be overlap among the species in their periods of activity. In areas with mild winters the flies may be active throughout the year. In colder regions fly activity ceases with the first frost and there is usually only a single generation per year. In these regions the second and third instars remain in the stomach over the winter.

Eggs are attached to hairs while the fly hovers close to the horse. Fecundity is roughly correlated to the size of the fly. *G. haemorrhoidalis* matures about 50–200 eggs, *G. nasalis* 300–500 eggs, and *G. intestinalis* up to 1000.[1] Eggs of the various species are laid in specific

locations and are attached in a specific manner, allowing identification of eggs to species. The eggs are laid on the horse's coat except for *G. pecorum* which lays up to 2000 eggs in batches of 100–200 on pasture plants. The eggs of *G. pecorum* and *G. haemorrhoidalis* are dark brown; the eggs of the others are yellow and are readily visible glued to the hairs, usually one to a hair. The eggs of *G. intestinalis*, the most common fly, are laid on the front legs, particularly the lower parts; those of *G. nasalis* in the intermandibular area; the others species' eggs are laid on the cheeks and lips.

The eggs are ready to hatch in about 2–10 days and the first instars enter the mouth either by host biting or licking or by subcutaneous migration from the cheeks into the oral cavity. The eggs of *G. intestinalis* and *G. pecorum* require a stimulus, provided by licking (moisture) or rubbing (friction), before they will hatch. The larvae penetrate oral mucosa, migrate to inner surfaces and emerge in the inter-dental spaces. The larvae of *G. intestinalis* penetrate the anterior end of the tongue and burrow in the buccal mucosa for about 3–4 weeks before invading pockets between the teeth or between the gum and molars.[2] *G. nasalis* may also accumulate in pockets alongside the molars and cause mouth irritation. *G. haemorrhoidalis* can penetrate the skin of the cheek and after wandering in the tissues of the mouth may attach in the pharynx. The second instar of *G. intestinalis* may also attach for a few days to the pharynx and the sides of the epiglottis before passing to the stomach. The first instars of *G. pecorum* burrow into the mucous membranes of the hard palate, cheek and tongue where they develop into second instars. They then move to the pharynx where they develop into the third instar.[3] Occasional larvae migrate to abnormal sites including the brain, the cranial sinuses, the heart, and lungs.

1585

1586

Third instars of *G. intestinalis* are found attached to the mucosa, usually in bunches, at the junction of the glandular and non-glandular portion of the stomach, where they become attached to the mucosa. *G. nasalis* larvae are found in the pyloric region of the stomach and the duodenum. *G. pecorum* larvae may be found in the pharynx and upper part of the esophagus and in the fundus of the stomach. *G. haemorrhoidalis* larvae are found in the tongue, the pharynx, and the gastric fundus.

In the host, two molts are made and the larvae pass out in the droppings 10–12 months after infestation, usually in the spring and early summer. Some larvae may attach temporarily to the rectal mucosa on their way through. The larvae migrate into the ground, pupate, and adult flies emerge after 3–5 weeks to recommence the late summer attacks on horses.

28.1.4

PATHOGENESIS

The adult fly causes considerable annoyance when ovipositing. The droning noise and the sudden attacks to lay eggs causes head tossing and running in the host. *G. nasalis* is particularly troublesome as it darts at the lips and throat.

There is some doubt as to the importance of the lesions associated with the larvae. At the sites where they adhere there is an area of thickening and inflammation and in rare cases gastric perforation occurs. It is probable that there is some chronic gastritis and interference with digestion in most infestations. *G. intestinalis*, the most common species, attaches to the squamous epithelium and this has a relatively slight impact on digestion in the horse. However, the ulceration, edema, and abscessation associated with this species cannot be overlooked and one must expect some effect from such lesions although it is difficult, in practice, to separate these findings from those associated with a concurrent worm burden. Occasional perforation of the gut has been documented.[4] The larvae do not remove sufficient blood to cause anemia, feeding mostly on tissue exudate. In rare cases pleurisy may occur following perforation of the esophagus close to the cardia.[5] In very heavy infestations with *G. pecorum* the presence of large numbers of larvae (100–500) on the soft palate and base of the tongue can cause stomatitis and some deaths. Migration of first instars in the tongue and interdental gingiva and the aggregation of larvae in periodontal pockets may produce irritation or pain and may prevent foals eating.

28.1.5

CLINICAL FINDINGS

A non-specific syndrome of unthriftiness, poor coat, occasional mild colic, and lack of appetite, plus bad temper and unwillingness to work is usually ascribed to bot infestations. Adult flies frighten horses by their hovering, darting flight, especially around the head of the horse, and may be a cause of shying and balking.

28.1.6

CLINICAL PATHOLOGY

The eggs on the hairs can be seen by direct inspection but the presence of larvae in the stomach and intestines can only be detected after treatment with a suitable boticide.

28.1.7

NECROPSY FINDINGS

A few larvae are present in the stomach of most horses at necropsy but clinical illness is usually associated with very large numbers. The areas of larval attachment are pitted and the gastric wall thickened. There may be an adhesive peritonitis with attachment and abscessation of the spleen over such areas.

28.1.7.1

DIFFERENTIAL DIAGNOSIS

The syndrome produced is not sufficiently characteristic to make antemortem diagnosis possible and bot infestations are commonly associated with helminth infestations which produce most of the signs observed. A tentative diagnosis of infestation of the gums can be made by signs of pain on mastication and the presence of bot-fly eggs on the horse at that time. A variety of serologic tests, including an ELISA, have been evaluated[5] and found to be generally specific and sensitive. There has been no further development of a practical test. Endoscopy using a video gastroscope has been applied to the diagnosis of gasterophilosis, although its use has been confined to use in drug efficacy studies.[6]

28.1.8

TREATMENT

Many of the organophosphates are effective. Trichlorfon 40 mg/kg is effective and is usually given with a benzimidazole to control strongyles as a common broad-spectrum mixture in the horse. It can also be used as a paste. Ivermectin 0.2 mg/kg has high efficacy against the oral and gastric *Gasterophilus* larvae[7] as well as all gastrointestinal nematodes, including migrating and hypobiotic large strongyles, microfilaria of *Onchocerca cervicalis* and larval stages of *Habronema* spp. and *Draschia megastoma* in the skin. Ivermectin has gained high acceptance in horse practice. Moxidectin 2% oral gel has been shown to have excellent efficacy.[6,8]

28.1.9

CONTROL

Treatment should preferably be administered after fly activity has ceased and the larvae have reached the stomach but before gastric damage has occurred. In most districts two doses should be given in winter, or in late winter and early spring. In foals showing pain on mastication, treatment with ivermectin paste or dichlorvos should be given as needed throughout the fly season.

The use of repellents or agents to kill the larvae in manure has not been successful, nor has bathing the affected hairs to encourage mass hatching and death of the larvae. The use of fringes, veils and tassels on the head harness helps protect horses against fly worry but is of little use in preventing bot infestation.

28.2 *OESTRUS OVIS* INFESTATION (NASAL BOTS)

Infestation of sheep and goats with larvae of the nasal bot fly has a serious effect on the productivity and welfare of both sheep and goats. Adult activity induces stress responses and significant behavioral change. Larval infestation induces moderate to severe pathology that reduces productivity.

Similar flies are known to affect horses, donkeys, and mules (*Rhinoestrus* spp.) in the Mediterranean region and to affect camels (*Cephenemyia titillator*) in Africa as well as Australia. Wild ungulates are affected by nasal bots (e.g. *Cephenemyia* spp.). Very little is known about the pathology and impact of these later groups of flies, but similarities in life history suggest their affects will be similar to that discussed below.

28.2.1 Synopsis

28.2.1.1 Etiology

One species, *Oestrus ovis*, which inhabits the nasal passages and sinuses of sheep and goats.

28.2.1.2

Epidemiology

Larvae are sprayed onto the nares of hosts by passing females. Flies are active during spring and summer, inducing behavioral changes in hosts under attack. In temperate climates there is only a single generation per year, but in warmer climates two generations are known. First instars in the nasal passages undergo hypobiosis during winter or hot summer when survival of pupae or adults is low, resuming development when conditions are more favorable.

1586
1587

28.2.1.3

Clinical signs

Shortly after arrival of the larvae an increase in nasal discharge and sneezing are evident. As the infestations develop the amount of discharge increases and the nostrils may become caked with dust and debris forcing the infested animals to breath through their mouth.

28.2.1.4

Clinical pathology

Changes are noted to the mucosa of the ethmoid and sinus regions. Inflammation of these surface tissues is evident and increases as the larvae become mature. Changes to the epithelial structure are noted including the erosion of the surface ciliary covering and a breakdown in epithelial cell integrity. Abrasive action of the body armature as well as the activity of proteolytic enzymes excreted/secreted by the larvae are responsible for the pathology. Secondary effects Include the induction of lung lesions and the activation of latent ‘orf’ infections. Diagnostic confirmation. Behavioral changes during fly season and nasal discharge.

28.2.1.5

Differential diagnosis

Unthriftiness usually associated with helminth infection.

28.2.1.6

Treatment

Macrocyclic lactone endectocides, clorsulon.

28.2.1.7

Control

Treatment given when fly activity has ceased.

28.2.2

ETIOLOGY

A single species, known as the sheep nose bot, affects sheep and goats in most regions, but is particluarly significant in the Mediteranean basin, central America southern Africa, and eastern Europe. The larvae inhabit the nasal passages and sinuses, eventually being expelled through the nares. Goats are less dramatically affected than sheep. The slightly dorso-ventrally flattened, segmented larvae are light cream in color, but as they reach maturity dark bands appear on each segment.

28.2.3

LIFE CYCLE AND EPIDEMIOLOGY

The adult fly is stout, mottled gray in color, and about 1 cm long. Its mouthparts are rudimentary and it does not feed. In North America, flies emerge in the late spring, mate, and the females begin larviposition activities approximately 2–3 weeks later.[1] Adult flies attempting to deposit larvae on the nares annoy the sheep and cause them to bunch or seek shelter. Stamping of the feet and shaking of the head are common. Sheep may bunch together and press their heads into the fleece of others. Fly activity occurs primarily during the warmer parts of the day, but still may result in the loss of a good deal of grazing time. Behavioral changes in goats are less dramatic,[2] presumably because of their browsing habit.[2]

Larval development takes place within the dorsal turbinates and frontal sinuses. The period of development can vary from 3 weeks to several months after which they migrate to the nostrils. Larvae feed on the mucosal secretions and cells eroded from the mucosal epithelium. The larvae are thick, yellow-white in color and when mature there is a dark dorsal band on each segment. The ventral surface has rows of small spines on each segment. Mature larvae exit the host, usually during a bout of sneezing, and actively burrow beneath the upper layers of soil and ground litter. Pupation occurs at these locations and development of the adults requires 4–5 weeks, but may take longer at low temperatures.[3] In temperate areas there may be one or two generations per year but several generations may be completed in hot areas. *O. ovis* are adapted to the various climates prevailing wherever sheep and goats are kept. When winters are cold, the larvae can overwinter by remaining dormant in the first instar (hypobiosis), but in warmer climates development may continue throughout the winter. In those regions where summer temperatures are extreme the larvae will also undergo hyopobiosis.

O. ovis are an important zoonosis as the females may larviposit in the eye, nose or on the lips of humans. In some countries ophthalmomyiasis or infection of the upper respiratory tract is a common occurrence.

28.2.4

PATHOGENESIS

The stress of the larviposition attacks can be significant with reduced grazing time and over-heating resulting from bunching. Herdsmen find the animals are more nervous and difficult during the fly activity periods.

Larvae induce a gradually increasing rhinitis and sinusitis as the infestation persists. Marked changes in the structure of the epithelial tissues are noted with a marked cellular degeneration and a loss of the ciliary layer. The changes are a result of both mechanical activity of the larval spines and mouthhooks as well as the effect of proteolytic enzymes excreted or secreted.[4] Varying degrees of mucous discharge are observed in the later stages of the infestation. This can lead to the nostrils being occluded by adherent straw and dust.

28.2.5

CLINICAL FINDINGS

Early in the infestation there is a distinct rhinitis accompanied by a muco- to muco-purulent discharge. Later as larvae mature, a sinusitis is evident. Presence of mature larvae in nasal cavities may induce excessive sneezing which assists larval exit.

Activity of the larvae in the nasal cavities and the changes they induce lead to an increased incidence of secondary pathology. The number and severity of lung abscess are more significant in nose bot infested sheep.[5] The presence of bots also is correlated with increased carcinomas[6] and may lead to reactivation of latent ‘orf’ symptoms.

28.2.5.1

DIFFERENTIAL DIAGNOSIS

The behavioral changes during fly activity, including bunching and burying of noses in neighbors' fleece is a reliable indicator of fly attack. Nasal discharge and excessive sneezing are highly suggestive, but not definitive. Infested sheep and goats develop some level of immunity form exposure to larval antigens. An ELISA for detection of antibodies to larvae secretions has been developed.[7]

28.2.6 TREATMENT

Closantel 7.5 mg/kg[8] and ivermectin 0.2 mg/kg[9] as well as other macrocyclic lactones[10,11] are effective and the use of these compounds for fluke or worm control also controls nasal bots.

28.2.7 CONTROL

Treatment should preferably be applied after the cessation of fly activity, although it may be necessary to apply treatments during prolonged fly activity in order to give relief.

28.3 *HYPODERMA* SPP. INFESTATION (WARBLE FLIES)

Infestations of cattle with the larvae of *Hypoderma* spp. cause serious damage to hides and carcasses, as well as production losses. Occasional deaths from anaphylactic shock or toxemia and damage to the central nervous system or esophagus. Several other flies with very similar life histories similarly affect goats (*Przhevalskiana silenus*), and semi-domestic reindeer (*Hypoderma tarandi*) in addition to affecting the well-being of wild ruminants.

28.3.1 Synopsis

28.3.1.1 Etiology

Hypoderma bovis and *H. lineatum* in cattle, *H. sinense* in cattle and *yaks, H. diana* in deer, *H. tarandi* in reindeer and caribou, *Przhevalskiana silenus* in goats. Horses are occasionally affected.

28.3.1.2 Epidemiology

Eggs attached to hair in spring to late summer, larvae penetrate skin and migrate to esophagus (*H. lineatum*) or spine (*H. bovis*) where they stay for 6–7 months; they then move to subdermal tissue along the back and after 2–3 months emerge from the breathing hole, fall to the ground, pupate and emerge as adult flies 3–5 weeks later. 1587 1588

28.3.1.3 Clinical signs

Poor growth and production. Larvae in the back causes obvious swellings while larvae in the spinal cord may cause posterior paralysis. Treatment of larvae while they are in the esophagus may cause massive edema, and edema and paraplegia may occur if animals are treated when larvae are in the spinal canal.

28.3.1.4 Clinical pathology

An ELISA is available.

28.3.1.5 Lesions

Larvae are found in discolored tissue.

28.3.1.6 Diagnostic confirmation

Swellings along back characteristic. Paraplegia occurs about 72 hours after treatment.

28.3.1.7 Differential diagnosis

Traumatic injury to the spine; aberrant *S. vulgaris* larvae in the horse.

28.3.1.8 Treatment

Organophosphates, macrocyclic lactone endectocides.

28.3.1.9

Control

Treatments are given so as to *avoid* treating when larvae are in the esophagus or spinal canal. (Usually treated in autumn and spring but varies with location.)

28.3.2

ETIOLOGY

There are two species which specifically parasitize cattle: *Hypoderma bovis* and *H. lineatum*. A third species, *H. sinense*, affects cattle and yaks in central Asia.[1] The adult flies are robust and hairy, about the size of a bee (12–18 mm long), are yellow-orange in color and have two wings. They are not easily seen because of the rapidity of their flight. Repeated infestation results in an acquired immunity that results in older animals being less severely affected than younger animals.

Horses are occasionally infected with *Hypoderma* species of cattle. The larvae are found in subcutaneous cysts on the back, but have not been reported to complete development. This location causes problems if they are in the saddle region.

Losses to the cattle industry associated with warble fly have not been estimated recently, but in 1965 the loss was estimated to be US$192 million per annum in the United States, and in 1976 approximately CAN$100 million in Canada. In 1982 the cost of warble fly was estimated as £35 million for Great Britain, but the parasite has now been eradicated from the UK and Ireland. Advent of the macrocyclic lactone endectocides have greatly reduced the prevalence of the cattle species in North America, but they persist in localized areas.[2]

Hypoderma tarandi, *H. acteon*, and *H. diana* infect reindeer/caribou and deer respectively. *H. diana* is found throughout Europe in several deer species but may also occur in sheep. *H. actaeon*, also found throughout Europe, is known only from the red deer. These species do not undergo deep tissue migrations that characterize the lifecycle of the cattle species.

Przhevalskiana silenus is similar to the above and parasitizes goats in the Mediterranean basin, parts of eastern Europe as well as in Pakistan and India. This species also does not have a deep tissue migration and larvae tend to develop subcutaneously very near the site of initial skin penetration. The losses resulting from this parasite are significant and result from reductions in carcass quality and reduced animal health.

The larvae of *Dermatobia hominis*, a small (12 mm long) related fly, parasitize a wide variety of hosts and cause major economic losses to cattle production in South America.

They also affect man and are a major zoonosis for travelers in the region. Mature larvae are about 2.5 cm long and develop in a subcutaneous cyst that can be quite painful. Female *Dermatobia* oviposit on zoophilous, 'porter' flies such as mosquitoes and stable flies which they catch 'on the wing'. The eggs are transported to mammalian hosts where they hatch in response to increased temperature as the fly lands. Larvae penetrate the skin, but do not migrate. Treatment and control measures are the same as for *H. bovis*.

28.3.3 LIFE CYCLE AND EPIDEMIOLOGY

Warble flies are common parasites of cattle in the northern hemisphere, including North America, Europe, and Asia. Precise distribution of these parasites have been changing recently with the widespread use of macrocyclic lactone endectocides and the adoption of eradication programs in many European countries. Infestations south of the equator are rare and are the result of imported cattle, although endemic cases have occurred in Chile.

Adult flies are active in the spring to late summer, *H. lineatum* usually appearing 3–4 weeks before *H. bovis*. *H. lineatum* attaches up 600 eggs, in strings of 5–25, to hairs on the legs or lower parts of the body while *H. bovis* attaches eggs, one at a time, to hairs on the rump and upper parts of the hindleg. The oviposition flight of *H. bovis*, darting in to lay each egg, will terrorize cattle. Eggs hatch in 4–6 days. The larvae penetrate the skin using protease enzymes and migrate through connective tissues to reach the esophagus (*H. lineatum*) or the epidural fat in the spine (*H. bovis*) where they stay, feeding and growing, for 2–4 months. They subsequently continue their migration to reach the subdermal tissue of the back in the early spring. Here they make a breathing hole and become encased in a granulomatous cyst. They complete development in 1–2 months, passing through second and third instars and emerge through the hole, fall to the ground and pupate. Adult flies emerge some 3–5 weeks later. The fully developed larvae are thick and long (25–30 mm), light cream in color, but darkening to almost black as mature third instars. A single animal may have up to 300 larvae each developing with granulomatous cysts, with breathing holes, under the skin of the back.

The timing of the life cycle, i.e. the period when grubs are present in the animals and the time at which the flies are present in large numbers, varies with the climate and is of importance in a control program. *H. lineatum* generally is 1–2 months ahead of *H. bovis* and where the two flies are present both 'grub' and 'fly' seasons may be very long. In the southern United States the 'fly season' is February and March; in Canada it is June to August. The period when grubs are present in the back is December in the south and

February to May in Canada. In Europe the larvae begin to move to the back in January to July.

28.3.4 PATHOGENESIS

Migrating first instars cause little damage as they use their proteolytic enzymes to migrate through connective tissue. The enzymes, however, have an anti-inflammatory effect, partially through cleavage of complement components.[3] Larvae maturing under the skin of the back form holes in the skin and the reaction of the host encloses each grub within a granulomatous cyst. On rare occasions an anaphylactic reaction may occur in a sensitized animal as the result of death of migrating larvae; chance migration into the brain may also occur. Intracranial myiasis due to *H. bovis* has also been recorded in the horse. Treatment of animals when the first instars are in the esophagus may cause a massive inflammatory edema which may prevent feeding and swallowing of saliva; eructation may stop and bloating may occur. Treatment of *H. bovis* while it is in the spinal canal may also cause edema and mild to severe paraplegia.

28.3.5 CLINICAL FINDINGS

If the fly population is heavy, cattle at pasture may be worried by their attacks which disrupt grazing and breeding behavior. Avoidance behavior, called gadding, may result in injury as cattle run into fences and other natural obstructions. Heavy infestations with larvae are commonly associated with poor growth, condition and production but such heavy infestations are often complicated by other forms of mismanagement including malnutrition and parasitic gastroenteritis. Immunosuppression results from the effect of larval secretions. Infected cattle milk poorly and a considerable increase in milk production and milk fat occurs after treatment.

The presence of the subcutaneous larvae causes obvious swelling with pain on touch. The swellings are usually soft and fluctuating. There may be as many as 200–300 such lesions on the back of one animal.

With involvement of the spinal cord there is a sudden onset of posterior paralysis without fever and without other systemic signs. The suddenness of onset and the failure of the disease to progress usually suggest traumatic injury. A similar disease can occur in horses and is reputed to be more common in horses than in cattle.

28.3.6

CLINICAL PATHOLOGY

An ELISA which detects antibodies to the secreted enzymes of *H. lineatum* and *H. bovis* has been developed. It has been used in the eradication program in Great Britain[4] and in France.[5] In addition, an antigen capture ELISA, used to detect the presence of circulating quantities of the predominant larval enzyme has been developed.[6] This will be useful in differentiating active from cleared infestations and will be useful in detailed surveillance programs.

28.3.7

NECROPSY FINDINGS

The first instars, migrating within connective tissue, are usually surrounded by a zone of yellow-green discoloration. Later larval stages lie in a subcutaneous, granulomatous cyst which may contain a pale fluid. Rarely the cyst will contain a large amount of purulent discharge.

28.3.7.1

DIFFERENTIAL DIAGNOSIS

- No other disease causes the characteristic swellings on the back
- The differential diagnosis of posterior paralysis and anaphylaxis are discussed in detail under the respective headings of disease of the spinal cord and anaphylaxis
- The clinical signs of organophosphorus poisoning usually occur within 12–24 hours following application of the compound
- Posterior paralysis due to destruction of the larvae in the epidural space usually occurs approximately 72 hours after application of the organophosphorus insecticide.

28.3.8

TREATMENT

28.3.8.1

Organophosphorus compounds

Organophosphorus insecticides kill migrating larvae and can be applied by spray or a ‘pour-on’ technique, by individual oral dosing or by mixing in the feed. They are highly effective, but unless used in strict accordance with the recommendations of the manufacturer damaging side-effects may occur.

The time of their administration is regulated by the stage of larval development and their location within the host. Hence the timing varies with climate. The emphasis is to deliver treatment shortly after all eggs have hatched and larvae are small and their death releases the least amount of enzymes into the host system. If treatment is delayed until these larvae have reached their maximum size, the sudden release of large amounts of proteolytic enzymes causes tissue damage that results in severe swelling. This swelling and inflammation affect the function of the esophagus (*H. lineatum*) resulting in bloat or swelling around the spinal chord leading to hind quarter paralysis (*H. bovis*). Severity of the reaction also appears to be related to the number of larvae present. These insecticides are not effective against second and third instars within the subcutaneous cysts.

Application in the form of a spray should insure that the skin is wetted by using a pressure spray (20–30 kg/cm^2), and spraying the flat body surfaces such as the neck, back, shoulders, sides, and thighs. Use of a low pressure spray or wash should be followed by vigorous use of a curry comb or brush. Pour-on applications should be made carefully along the midline in a thin stream which penetrates the hair coat.

Although these compounds disappear very quickly from tissues, recommendations are that they should not be administered to milking animals, and beef animals should not be slaughtered for at least 60 days after dosing. Milking cattle with back lesions can be treated with derris dust (containing rotenone) but this must be brushed in vigorously or sprayed under pressure so that the material penetrates to the larvae.

Toxic effects of organophosphates have been described elsewhere. The pitfalls in their use in warble control are related chiefly to the time of administration.

28.3.8.2

Macrocyclic lactone compounds

All larval stages of cattle grubs are very sensitive to these endectocides. Their widespread use in nematode control programs plays a major role in controlling warble flies. They remain effective for about 4 weeks.[2]

28.3.8.3

Manual removal

When small numbers of cattle are affected with relatively few warble grubs, manual removal of the larvae is practised. Incomplete removal or breaking the larvae during removal may cause a severe systemic reaction. This reaction and the one which sometimes

occurs after systemic treatment of cattle infected with warble fly have been ascribed to anaphylaxis. However, there is evidence that it is due directly to toxins liberated from dead warble maggots and that phenylbutazone may control this toxin.[3] The clinical signs include dullness, salivation, lacrimation, dyspnea, wrinkling of skin on the side of the neck, and edema under the jaw.

28.3.9

CONTROL

While rotenone has been used successfully to kill the larvae in the subcutaneous tissues in the back, this technique does not prevent damage to the hide and has been largely superseded by the use of organophosphate insecticides and the macrocyclic lactone endectocides. In general, systemic treatments are given in the autumn (between September 15 and November 30) and in the spring after March 1.

Warble fly has been eradicated in Norway, Sweden, Denmark, Malta, Ireland, and Great Britain. Eradication programs have commenced in France. A joint Canadian–US study using sterile male *Hypoderma* species eradicated these species from the test area, but the difficulty of mass producing flies, in the absence of an in vitro rearing system, makes this technique impractical for large scale warble fly control.[7]

Vaccination of cattle using crude larval extracts has reduced both the number of warbles in the back and the number of larvae that could pupate.[8] Results of vaccination studies with recombinant antigens have been variable,[9] but show promise although there has been no commercial development.

28.4 Cutaneous myiasis

Cutaneous infestation by fly larvae or maggots (known as myiasis) causes serious loss to the livestock industries across the world. Losses include mortality, increased morbidity and reduced production of meat, milk, and fiber. The disease is associated with larvae of flies in two major dipteran families, Calliphoridae and Sarcophagidae.

Two types of cutaneous myiasis can be distinguished; primary, in which the fly larvae are obligate parasites feeding on living tissues and secondary, in which the larvae feed primarily on necrotic tissues and only secondarily invade uninjured tissue. Clearly, primary myiasis is most significant to animal health and therefore the most costly, not only in terms of mortality, morbidity and reduced productivity, but in terms of cost of control. However, it may be difficult to differentiate primary from secondary myiasis because the larvae are superficially similar. 1589 1590

Three primary fly strike disease states, resulting from the activities of different species, are well known and described. Blowfly strike by calliphorids such as *Lucillia cuprina* and *L. sericata* is a major problem, particularly for sheep producers, in Australia, New Zealand, and Great Britain. The second group are the screwworms, *Cochliomyia hominovorax* (in the New World) and *Chrysomyia bezziana* (in southern Europe, Africa, and Asia) which are of importance across the livestock species and result in great costs for control. The sarcophagid (flesh fly) *Wohlfahrtia magnifica* causes traumatic myiasis in a wide range of livestock species, but has most impact in goat and sheep production. This species occurs in southern Europe, particularly the Mediterranean and the steppe regions of the continent. Because of differences in the nature of the disease state and control practices for each of these three groups they will be dealt with as separate entities.

28.4.1 BLOW FLY STRIKE

The cost of blow fly control and production losses in Australia for 1985 have been estimated as $200 million. A review of blow fly strike in Australia has been published and is given here as a review reference. Blow fly strike is a very important cause of losses in sheep in most countries where large numbers are kept. In bad years many sheep may die (up to 30% of a flock) and the expense of controlling the flies and failure of wool to grow after recovery may be a serious strain on the local sheep economy. Merino sheep, especially those with heavy skin wrinkles, are by far the most susceptible breed.

28.4.1.1

Synopsis

28.4.1.1.1

Etiology

Lucilia cuprina and *L. sericata* are the most important primary flies while other calliphorids act as secondary invaders.

28.4.1.1.2

Epidemiology

Fly numbers depend on temperature. Flies are attracted to wool that has been wetted or to areas affected by fleece rot, mycotic dermatitis, diarrhea or urine staining. Incidence of strike is positively correlated with fly numbers, rainfall, humidity, cloud cover, and pasture growth. Covert strikes provide larvae for future generations.

28.4.1.1.3

Clinical signs

Sheep are restless, bite at the affected area, and wriggle their tails. Affected area is moist and malodorous, body temperatures may reach 42°C, pulse and respiratory rates increase.

28.4.1.1.4

Clinical pathology

A clinical examination is all that is necessary.

28.4.1.1.5

Lesions

Moist, malodorous areas containing active larvae. Predisposing diseases such as dermatophilosis, fleece rot, parasitic gastroenteritis, and footrot are easily identified.

28.4.1.1.6

Diagnostic confirmation

Clinical signs are diagnostic.

28.4.1.1.7

Differential diagnosis

Lice, sheep scab, screwworm fly infestations.

28.4.1.1.8

Treatment

Organophosphates, macrocyclic lactone endectocides, or cyromazine.

28.4.1.1.9

Control

Cyromazine or triflubenzuron protect for 10–12 weeks while organophosphates kill larvae and protect for 2–3 weeks. Breeding for resistance and control of predisposing diseases is important. Conduct mules operation on lambs at marking, cut tails to the correct length, institute a proper gastrointestinal nematode control program, and give a mid-season crutching to control breech strike.

28.4.1.2

ETIOLOGY

Despite there being a large number of species capable of causing the disease, grouped geographically below, there are two species that are the primary agents of blow fly strike: *Lucilia cuprina* and *L. sericata*.

- Australia: *Lucilia cuprina, L. sericata, (Calliphora stygia, C. novica, C. augur, C. hilli, C. albifrontalis, Chrysomyia rufifacies, Ch. varipes)*
- *Lucilia sericata, L. cuprina, (Calliphora stygia)*
- Great Britain and northern Europe: *Lucilia sericata (Calliphora erythrocephala, C. vomitoria, Phormia terraenovae)*
- North America: *(Phormia regina, P. terra-novae)*.

28.4.1.3

LIFE CYCLE AND EPIDEMIOLOGY

The primary agents of fly strike are obligate parasites. *Lucilia cuprina* is overwhelmingly important in the initiation of strike in sheep from Australia, and South Africa. *L. cuprina* was introduced to New Zealand in 1988 and fly strike is now a major disease in that country. In northern Europe the primary agent of fly strike is *Lucilia sericata* although there are some other minor species that have been reared from struck sheep.[1]

In sheep, the incidence varies widely depending largely on the climate, warm humid weather being most conducive to a high incidence. In summer rainfall areas fly strike may be seen most of the year, being limited only by dry winter conditions; while in winter rainfall areas it is usually too cold in the winter and too dry in the summer for outbreaks to occur. Under these conditions abnormally heavy summer or autumn rains may be necessary before an outbreak will occur.

28.4.1.3.1

The fly population

Primary flies are of particular importance as these initiate the strike and provide suitable conditions for subsequent invasion by secondary flies. These latter flies are not of economic importance but may infest wool matted with dried exudate or feed on necrotic tissue surrounding healing strike. In warm areas pupal development may continue throughout the year but as soil temperatures fall an increasing number of larvae fail to pupate and larvae may overwinter until the following spring. In the spring adult flies emerge and after one or two breeding cycles, numbers build up to a peak in summer. Numbers may remain high if climatic conditions are suitable, moisture being of prime importance, but may fall dramatically in hot dry conditions. An increase in numbers may occur again in the autumn.

All adult flies require carbohydrate and water, but females require protein for ovarian development. The flies are attracted to sheep that have undergone prolonged wetting so that bacterial decomposition of the skin has occurred. The association of fly strike with fleece rot, mycotic dermatitis, diarrhea, urine staining, and footrot is related to the excessive moisture deposited on the skin or to the production of serous exudates. Fractions of *Pseudomonas aeruginosa* infected fleece have been shown to stimulate oviposition.[2] *Lucilia cuprina* deposit eggs in batches of up to 300, the actual number depending on the fly's size and its ability to locate sufficient protein for egg development. Similarly, *L. sericata* deposit eggs in batches of approximately 200. The average female longevity in the field in Australia is about 2 weeks and females rarely live long enough to mature more than two or three batches of eggs. In the UK mean female longevity is shorter at 5 days.

The eggs hatch in 12–24 hours and the first instars feed on protein-rich serous exudate that has been provoked by bacterial damage or some other irritation. Larval mouthhooks and enzymes present in the saliva and excreta will further digestion of the skin. Large groups of larvae, particularly second and third instars, further damage of the skin which extends the lesion and insures a continuing supply of food. The second and third instars are 6–12 mm long, thick, yellow and white in color and move actively. Larvae reach maturity after approximately 72 hours. They leave the feeding lesion, fall to the ground, wander briefly and then burrow into the earth to pupate. The length of the life cycle is highly temperature dependent; it be completed in as little as 8 days but may require up to 6 weeks in temperate regions such as the UK.[2] Eggs and larval stages are highly

susceptible to desiccation and morality will be high if the relative humidity in the fleece falls below 60%. In temperate climates such as the UK, as photoperiods decline the larvae that have left the host, will burrow into the ground and cease development, thereby overwintering as mature larvae.

Several generations of primary flies are necessary before numbers are high enough to cause severe outbreaks and therefore warm humid weather must persist for some time before severe outbreaks occur. The incidence of body strike increases with the increase in the number of gravid flies and is positively correlated with rainfall, cloud cover, and rate of pasture growth.[3] Other primary flies are not as effective as *L. cuprina* in initiating a strike, and in Australia at least 85–90% of all primary strikes are due to *L. cuprina*. Larvae of primary flies, other than *L. cuprina*, and secondary flies develop in carrion or in rotting vegetation and their main role is to invade and extend the primary strike. *Ch. rufifacies* is the most important secondary fly in Australia. It requires higher temperatures than the other flies, is found later in the season and is the first to disappear as temperatures fall.

Detailed population models have been developed for the strike by *Lucilia* spp. in Australia[4] and northern Europe[5] and both have been used to predict onset of fly strike in sheep populations. The latter model has been extensively validated and is sufficiently accurate to establish an early warning system for alerting producers of the impending onset of fly strike and thus allowing well timed prophylactic treatments.

Distribution of fly strike in flocks is highly aggregated with a small number of sheep having high numbers of larvae in lesions, a moderate number of sheep with low numbers of larvae and the majority of sheep being unstruck.[6] In part this is a result of the attractiveness of already struck sheep to ovipositing flies, although other factors such as innate attractiveness play a role.

28.4.1.3.2

Susceptibility of sheep

By far the most common site for fly strike is the breech: infestation occurs here because of soiling and excoriation by soft feces and the urine of ewes. Lush pasture, parasitic gastroenteritis and fleece length are predisposing factors but individual sheep are predisposed because of the conformation of this part of their anatomy. Excessive wrinkling of the skin on the back of the thighs and the perineum, a narrow perineum and crutch and an excessively long or short tail favor continuous soiling of the area and

encourage ‘crutch or breech strike’ or ‘tail strike’. Less common sites for infestation are around the prepuce (‘pizzle strike’), on the dorsum of the head when there is excessive folding of the skin (‘poll strike’), and along the dorsum of the body (‘body strike’) in wet seasons when fleece rot or dermatophilosis is common. Sheep grazing on tall, dense pasture are commonly affected by body strike because of the way in which the wet plants keep the fleece on the lower part of the body wet. Wounds, especially castration incisions, docking wounds and head wounds on rams caused by fighting, are also likely to provide good sites for blow fly strike. Young sheep are more susceptible.

28.4.1.4

PATHOGENESIS

The first instars feed on the exudate produced by the bacterial infection on the skin, but the larvae also produce excretory/secretory enzymes which may cause some skin degradation after egg hatch and provide soluble molecules on which the first instars can feed.[7,8] Later instars can cause severe skin damage to provide themselves with food. Larvae may also migrate from the original area of strike, along the surface of skin to establish additional focal lesions.

Many primary strikes remain small and are unnoticed by the farmer.[6] Such covert strikes may outnumber overt strikes and are important as a source of future generations of flies. Once the initial strike is made, the site becomes suitable for the secondary flies that now invade and extend the lesion. The effects of strike include toxemia due to absorption of toxic products of tissue decomposition, loss of skin and subsequent fluid loss, and secondary bacterial invasion.

28.4.1.5

CLINICAL FINDINGS

Individual sheep may be ‘struck’ at any time provided they are in a susceptible condition. Massive outbreaks tend to be confined to periods of humid, warm weather and are therefore in temperate areas usually limited in length to relatively short periods of 2–3 weeks, but in sub-tropical areas characterized by summer rainfall severe strikes may occur over many months.

The clinical effects of ‘blowfly’ strike vary with the site affected but all struck sheep have a basic pattern of behavior caused by the irritation of the larvae. The sheep are restless, moving about from place to place with their heads held close to the ground and they become anorexic. They tend to bite or kick at the ‘struck’ area and continually wriggle their tails.

If the area is large there is an obvious odor and the wool can be seen to be slightly lifted above normal surrounding wool. The affected wool is moist and usually brown in color although in wet seasons when fleece rot is prevalent other colors may be evident. In very early cases the maggots may still be in pockets in the wool and not yet in contact with the skin. When they have reached the skin it is inflamed and then ulcerated and the maggots begin burrowing into the subcutaneous tissue.

Three days after the primary oviposition feed intake is reduced, rectal temperature rises to about 42°C (108°F) and pulse and respiratory rates increase. Some sheep may die. The wool may be too hot to handle as a result of the inflammation caused by the mass of maggots that can be seen when the wool over the strike is opened. When primary strikes are invaded by secondary flies, particularly *Ch. rufifacies*, the affected area is extended and the maggots may burrow deeply into the tissues. Affected sheep may lose their fleece over the affected area and may suffer a break in the remaining fleece. Tracts of discolored wool may lead to other affected areas of skin. As the struck area extends a scab forms over the center, the wool falls out and the maggots are active only at the periphery.

28.4.1.6

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

A clinical examination is all that is necessary to make the diagnosis but identification of the flies responsible may be important if epidemiology is being considered. Identification of larvae should be carried out by a specialist. Molecular techniques for accurate identification are available from specialists.[9] Preservation of the larval stages is critical to these techniques and larvae should be rapidly frozen or preserved in 70% ethanol. Fly trapping may not correlate with larval findings as not all flies are equally attracted by commonly used baits.

28.4.1.6.1

DIFFERENTIAL DIAGNOSIS

Attention will be drawn to affected sheep by their foot stamping, tail twitching, and biting at the affected part. Affected sheep can easily be diagnosed by finding the moist, malodorous, maggot-infested area. Many covert strikes may be present without producing clinical signs. Predisposing diseases such as footrot, wound infections, dermatophilosis and diarrhea resulting from parasitic gastroenteritis are usually easily detected and fleece rot is indicated by matting of the wool and discoloration.

28.4.1.7

TREATMENT

A local dressing containing a larvicide and an antiseptic is applied. The prevention of reinfestations is also an important aim and as repellents have been largely unsatisfactory, it 1591
has become apparent that the larvicide in a suitable dressing must be one with maximum 1592
retention in the treated area. Modern dressings usually contain organophosphate insecticides but most products do not kill all the organophosphate resistant larvae and some perform poorly even against susceptible larvae. Variations in effectiveness with the same compound sold by different companies is probably related to formulation.[10] Ivermectin at 0.03 mg/kg applied by hand jetting is highly effective in killing all larval stages.[11] Powder and liquid dressings containing diazinon, tetrachlorfenvinphos, propetamphos, and ivermectin are most generally favored.

Cyromazine, an insect growth regulator, is now widely used. It is particularly active against second and third instars, but is slow-acting and so live larvae may be seen in the fleece for some days after treatment.

28.4.1.8

CONTROL

Practical control of crutch strike in extensive farming areas depends on the use of the Mules operation to extend the bare areas around the perineum and tail, good worm control to prevent contamination of the perineal region, correct tail length and a midseason crutching. Control of strike in other situations is based on insecticidal treatment and treatment of wounds as they occur. Under conditions of extensive sheep raising, such as occur in Australia and South Africa and where climatic conditions are conducive to the development of the disease, the control of blow fly strike is a major undertaking and an extensive bibliography on the subject is available. Only a summary can be presented here.

The subject can be divided into three phases: reduction in fly numbers; prediction of fly waves followed by prophylactic crutching and application of larvicides; and reduction in susceptibility of sheep.

28.4.1.8.1

Reduction of fly numbers

Reducing the fly population has been of limited value as there are usually enough flies present to strike all susceptible sheep if suitable conditions are present. However, if the primary fly responsible for initiating strikes can be controlled the importance of

secondary flies is greatly reduced. The measures used include trapping, early treatment of clinical cases and the proper disposal of carcasses and wool waste. Biological control by the use of insects parasitizing blow flies has been generally unsuccessful. Trapping, provided the traps are carefully looked after and satisfactory baits are used, can reduce the number of blow flies.[12] Recent work with synthetic attractants have shown reduction of strikes by up to 55%,[13] which suggests this approach will make a good adjunct to the overall fly management practices.

It is important to identify clinically affected sheep, particularly those affected early in the season, and to treat the infestations. If these early season strikes are not treated they serve to multiply the fly population and outbreaks will occur later in the season. When affected areas are clipped, the clippings should be disposed of and larvae on the sheep destroyed with a suitable dressing.

Control by genetic means offers promise for long-term control. Chromosome translocation to produce reduced fertility in male flies and lethal mutants, such as flies with yellow or white eyes which will be blind under field conditions and die, has been reported.[14] This technique is logistically and economically feasible and more cost-effective than the irradiated male technique used for screwworm control, as only two or three early-season releases of males would be required rather than continuous release. Future development of transgenic males that would be useful in male-only sterile insect releases also shows some promise.

28.4.1.8.2

Prediction of fly waves

Sporadic cases of body strike may occur in sheep at any time and cannot reasonably be prevented, but if the environmental circumstances conducive to high fly populations and high susceptibility of sheep are recognized fly ‘waves’ can be predicted and short-term prophylactic measures taken. Warm, showery weather extending over several weeks allows several generations to be completed and sufficient flies to be available to cause an outbreak of strike. Once sufficient flies are present, an outbreak of cutaneous myiasis may occur whenever the sheep become susceptible. Warm humid weather, rain over 2–3 days, or grazing in long wet grass, may provide suitable conditions for the sheep to become susceptible to body strike. Sheep with yellow fleece, i.e. high suint content, comprised of pointed, thin staples less tightly packed and with a low wax content, would be most susceptible. Measurement of simple fleece values has been suggested as a means of predicting the susceptibility of flocks to fleece rot and flystrike. Sheep with long

fleeces are more susceptible and the time at which shearing is carried out may exert an influence on the frequency and severity of outbreaks.

Outbreaks of breech strike will occur if the sheep have diarrhea, or if ewes have urine splashing onto the breech area because the tails are too long. If an outbreak is predicted or has begun, 'crutching' and the prophylactic application of larvicides will reduce the severity of the infestation. 'Crutching' refers to clipping of the wool around the breech or crutch of the sheep to avoid it becoming wet with urine and feces and providing a focus of attraction for flies. It is carried out routinely before lambing and immediately prior to a strike wave but provides protection for no more than 6 weeks. All the wool from above the tail, to the posterior aspect of the thighs and down to the hocks, must be removed. Because of the labor and loss of wool involved most sheep farmers depend on prophylactic dressing with a larvicide.

Predictive models incorporating climatic and production components have been developed in the UK. These are used to give producers warning of impending fly strike (see above)

28.4.1.8.3

Treatment and prevention

Prophylactic treatment with a larvicide has been a major part of blow fly control for many years but the preparations used and the methods of their administration have undergone many important changes. The triazine, Vetrazin, gives 8–10 weeks of protection and can be applied by jetting, as a pour-on[15] or as a intraruminal slow-release bolus.[16] Triflubenzuron, another insect growth regulator, also gives good protection.[17] Their action is specific to dipteran larvae. It should be noted that they are slow to kill as they affect the development of the subsequent life cycle stage. Diazinon, tetrachlorfenvinphos, propetamphos, fenthion ethyl, coumaphos, and other organophosphorus insecticides are widely used, but the period of protection gained by their use has markedly declined as the resistance to these compounds has increased. Further, the organophosphorus insecticides may be degraded by *Pseudomonas aeruginosa*. However, most fly waves are of short duration, and if the insecticide is applied thoroughly at the time an outbreak commences, these compounds may still give sufficient protection to minimize losses.

Three avermectins and the synthetic pyrethroids act as oviposition suppressants. Deltamethrin is more active than the avermectins but the avermectins also produce

significant mortality in the adult flies. They can be applied to the fleece as pour-ons or by spray races to prevent egg-laying.

The methods of application include dipping, jetting, and tip spraying. Dipping has the advantage of thorough wetting but requires high equipment and labor costs. Jetting is still recommended for crutch strike and if the jetting piece is combed through the wool from the poll to the rump with the solution at high pressure (500–900 kPa), good control of body strike will also be achieved. Tip spraying, which is the deposition of a higher concentration of insecticide onto the tip of the fleece, is only of use with dieldrin or aldrin as it relies on the ability of these compounds to diffuse down the wool fibers. The latter compounds are now banned in most countries. Tip spraying is not effective with organophosphates.

1592

1593

It is recommended that sheep should be treated early in the spring. This protects sheep against the early season strikes, many of which are covert, and prevents the build-up of fly populations in spring and early summer which leads to outbreaks.

28.4.1.8.4

Reduction in susceptibility of sheep

The primary method for reduction of sheep susceptibility to fly strike is the Mules operation. This technique, originally developed to remove the wrinkled region of the breech has been modified to address concerns regarding animal welfare which must be balanced against the impact of fly strike. The technique is still recommended in the recently established codes of practice. Other good management practices are essential to prevention of fly strike. These include management of gastrointestinal nematodes to prevent scouring, tails cut to the correct length and a midseason crutching to reduce soiling that predisposes animals to strike. Pizzle strike will be reduced by the use of testosterone implants and by pizzle dropping (surgical separation of the preputial sheath from the belly) although this procedure may cause some difficulty at shearing unless the shearers are warned. Ringing (shearing of the pizzle area) will give 6–8 weeks protection. Fleece rot occurs most commonly on the withers of sheep, and the conformation that allows accumulation of moisture and the development of fleece rot and fly strike have been shown to be hereditary. Sheep with these faults should be culled. Although control is mainly a matter of management, in periods particularly suitable for fly strike the periodic application of an insecticide is still essential.

The modified Mules operation is best performed at marking (tailing and castration) as the lambs heal more quickly and suffer little, if any, setback in growth. Further,

minimum death rates due to fly strike and maximum wool weights are obtained when sheep are mulesed as lambs. The technique has been developed extensively in Australia and is not described in detail here. In the hands of an experienced technician the time required to improve the perineal topography need be no longer than 1–2 minutes. The improvement is permanent and reduces crutch strike by 80–90%. Mulesing is accompanied by some pain, but current data unequivocally establish the positive health and welfare benefits conferred upon sheep in the Australian environment. The protection gained by mulesing surpasses that afforded by breeding and is immediate and permanent.

The Mules operation is often supplemented by including a tail-strip operation in which a thin strip of woolled skin is removed from each side of the tail to above its butt. This results in a reduction of the amount of wool on the tail and less chance of fecal and urinary contamination. Since the introduction of elastic rings for castration and removal of the tail, a tendency has developed to remove the tail at the butt. This allows wool to grow in around the anus where it may become soiled and struck and, when combined with the Mules operation which slightly everts the vulva, has caused a dramatic increase in carcinomas of the mucocutaneous junction in the vulva. Tail stripping is important when tails are left at the longer recommended length, that is to the tip of the vulva. Docking so that the tail is of the correct length and so that a flap of ventral wool-less skin is left to seal over the stump is important. The latter can be effected by pushing the skin back with the back of the docking knife before severing the tail.

Removal of the wool and skin wrinkles from the breech of sheep by surgical means or by selective breeding reduces the susceptibility of sheep to crutch strike and when combined with:

Alternatives to mulesing are seen as highly desirable, but remain elusive. A breeding program aimed at the selection of plain-bodied animals suggests itself as a suitable control measure, but progress would be slow.

Vaccination of sheep with proteases and extracts of peritrophic matrix from the larvae causes retardation of larval growth and in some cases leads to larval mortality.[18] In practice it is difficult to envisage sufficient antibody being secreted through the skin to protect against the initial strike. However, it could reduce the number of third instars leaving the sheep and reduce subsequent fly numbers. Enhanced approaches utilizing recombinant proteins delivered cutaneously have shown additional promise.[19] Vaccination against *Ps. aeruginosa* to protect against fleece rot and the likelihood of body strike has given encouraging results.[20]

SCREWWORM (*COCHLIOMYIA HOMINIVORAX* AND *CHRYSOMYIA BEZZIANA*)

Cutaneous myiasis associated with the screwworm maggots has been a cause of great financial loss in livestock in the western hemisphere, Africa, and Asia. Deaths may be heavy in groups of livestock which are at range and seen infrequently.

28.4.2.1

Synopsis

28.4.2.1.1

Etiology

Cochliomyia hominovorax in the New World (New World Screwworm) and *Chrysomyia bezziana* (Old World Screwworm) in Africa and Asia.

28.4.2.1.2

Epidemiology

Eggs laid in fresh wounds. Flies most active at 20–30°C. Disease spread by dispersal of flies or transport of infested animals.

28.4.2.1.3

Clinical signs

Larvae invade the tissue producing characteristic large lesions containing mature larvae and foul smelling brown exudate.

28.4.2.1.4

Clinical pathology

Not applicable.

28.4.2.1.5

Lesions

Deep wound containing foul smelling brown material and third instars.

28.4.2.1.6

Diagnostic confirmation

Rows of spines are present on the anterior part of each segment of the third instar.

28.4.2.1.7

Differential diagnosis

No other disease causes such lesions.

28.4.2.1.8

Treatment

Ivermectin 0.2 mg/kg subcutaneously kills many larvae and provides protection for 16–20 days. Other insecticides used as gels or ointments twice weekly are also effective. Doramectin subcutaneously.

28.4.2.1.9

Control

Eradication has been achieved in North and Central America by the mass release of sterile males. Chemical attractant baits will reduce the prevalence of flies and strikes. Breeding and management procedures such as castration and shearing should be carried out in the cold weather.

28.4.2.2

ETIOLOGY

Larvae of the flies *Cochliomyia hominivorax* and *Chrysomyia bezziana* cause myiasis or 'screwworm disease' of animals. The flies are typical blow flies, *C. hominivorax* (New World Screwworm) being blue-green with an orange head; *Ch. bezziana* (Old World Screwworm) is of similar coloring. *C. hominivorax* occurs in the Americas, *Ch. bezziana* in the Persian Gulf, Africa, and Asia. The occurrence of *Ch. bezziana* in Papua New Guinea provides a constant threat to livestock on the Australian mainland. A similar fly is *Callitroga* (*Cochliomyia*) *macellaria* which is not a true 'screw-fly' in that the larvae feed only on carrion or necrotic tissues.

1593 1594

28.4.2.3

EPIDEMIOLOGY

The screwworm maggots are obligatory parasites with no host-specificity. Thus, all domestic and wild, mammals, marsupials, and birds are potential hosts. Females are attracted to fresh wounds where they will oviposit. The navel of a newborn animal is a favored site, but fresh accidental or surgical wounds, such as those produced by castration, docking, and dehorning, are readily infested. Wounds which have already been infested are markedly attractive to the flies because of their odor. In bad seasons the flies will lay eggs on minor wounds such as areas of excoriation, tick bites, running eyes, peeling brands, and on the perineum soiled by vaginal and uterine discharges in animals which have recently given birth. Injury is not necessarily a prerequisite for screwworm strike in sheep, which can be struck in the intact infraorbital fossa and vulva. Wool loss and tenderness may occur and the remaining fleece may be stained.

The development of the fly is favored by hot, humid weather. The optimum temperature range for *C. bezziana* is 20–30°C (68–86°F). Below this the flies become sluggish and at 10°C (50°F) and below the flies will not move. Temperatures above 30°C (86°F) can be tolerated provided shade is available. *C. hominovorax* is active all year in areas where temperatures exceed 16°C and disperses rapidly from these areas as the temperature increases in the neighboring colder areas. The disease can be spread either by migration of flies or their carriage in livestock ships or commercial aircraft,[1] by shipment of infested cattle or other livestock, and by movement of affected wildlife. The mean distance that *C. bezziana* can travel and deposit eggs is 11 km. The maximum distance is 100 km, but long distances are probably wind assisted. In the new environment the flies may die out if the climate is unsuitable or persist to set up a new enzootic area. Persistence of the fly in an area may depend upon persistence in wildlife or in neglected domestic animals, although the latter do not usually survive unattended for more than about 2 weeks.

In many enzootic areas it is common for the fly to persist in neighboring warmer areas during winter, returning to its normal summer habitat as the temperature rises. This pattern is exemplified by the introduction of screwworms into the southeastern United States in 1933 where they had not previously occurred. The flies died out in most areas in winter but persisted in southern Florida. In succeeding summers migrations of flies northwards caused outbreaks. The disease has since been eradicated from the area.

The disease is of importance in tropical and subtropical areas of Africa, Asia, North and South America, especially Central America, the Caribbean islands, Mexico, and American states bordering on Mexico. The prevalence of the fly in enzootic areas places severe restriction on the times when prophylactic surgical operations can be carried out.

The potential worldwide geographical distribution and abundance of *Ch. bezziana* has been assessed using a computer program. The differences in the observed global distribution and the potential predicted distribution indicate the areas at risk of colonization.[2]

28.4.2.4

LIFE CYCLE

The screwworm flies have a typical fly lifecycle with eggs, three larval instars, and a pupal stage. Females lay 150–500 white eggs in shingle-like clusters at the edges of fresh wounds. Larvae hatch in about 12 hours and penetrate the tissues surrounding the wound. The larvae preferentially feed on fresh, living tissue which is digested by regurgitation of a wide variety of salivary enzymes. Oviposition by other screwworm flies is encouraged by

the presence of larvae already in the wound. The larvae feed as a group and at their time of maturation will have created a deep lesion 10–12 cm in diameter. Larval development is complete in 5–7 days, after which they leave the wound and fall to the ground. These mature third instars burrow into the upper soil layers and pupate. On the ground, pupal development is highly temperature dependent requiring from 3–60 days. Emerging flies commence egg-laying in about 1 week, having completed the life cycle, under optimum environmental conditions, in less than 3 weeks. There may be 15 or more generations per year.

The temperature sensitivity of the pupal stage, which is unable to survive freezing for more than short periods, limits the distribution of this parasite. As with all flies pupal development is highly temperature regulated. The screwworm pupal development is inhibited at soil temperatures below 15°C (60°F). Temperatures below this point for more than 2 months cause death of the pupa. Thus the occurrence of the disease is limited to warm climates. Pupae are also affected by the moisture content of the soil. The emergence of adults is reduced when the moisture content is more than 50%, while temporary floods can drown pupae.

28.4.2.5

PATHOGENESIS

Following invasion of the wound a cavernous lesion is formed, characterized by progressive liquefaction, necrosis and hemorrhage. Anemia and decreased total serum protein results from hemorrhage into the wound. Secondary bacterial infection, toxemia, and fluid loss contribute to the death of the animal. Surviving calves frequently develop infectious polyarthritis.

28.4.2.6

CLINICAL FINDINGS

The young larvae invade the nearby healthy tissues vigorously and do not feed on necrotic superficial tissue. A profuse brownish exudate, composed of larval excreta, and host fluids, pours from the wound and an objectionable odor is apparent. This is highly attractive to other flies and multiple infestations of a single wound may occur within a few days. The resulting tissue damage may be so extensive that the animal is virtually eaten alive. Affected animals show irritation in the early phase of the infestation and by day 3 show pyrexia. Animals do not feed but wander about restlessly, seeking shade and shelter.

28.4.2.7

CLINICAL PATHOLOGY

It is imperative to differentiate screwworm infestation from infestation with other fly larvae. The appearance and smell of the wound are significant but careful examination of the larvae is necessary to confirm the diagnosis. Mature larvae are 1–2 cm long and pink in color; they are pointed anteriorly and blunt posteriorly; two dark lines are visible reaching from the blunt posterior to the middle of the body and they have rows of dark fine spines on the anterior part of each segment. Specimens forwarded to a laboratory for identification should be preserved in 70% alcohol.

28.4.2.8

NECROPSY FINDINGS

Superficial examination of infested wounds is usually sufficient to indicate the cause of death.

28.4.2.8.1

DIFFERENTIAL DIAGNOSIS

The presence of maggots in the wound is usually apparent. It is important to differentiate them from blow fly larvae as described above.

28.4.2.9

TREATMENT

Affected wounds should be treated with a dressing containing an efficient larvicide and preferably an antiseptic. The larvicide should be capable of persisting in the wound for some time to prevent reinfestation. A number of proprietary preparations and some of the newer insecticides have been compared.[3] Lindane 3% and coumaphos 3% were the most effective but fenchlorphos 2.5%, diazinon 1.5%, chlorfenvinphos 0.05% and fenthion-methyl 0.2% were also very efficient. Stirofos (15%) and dichlorvos (20%) give season-long protection in the ears of cattle against *C. hominivorax* and *Amblyomma maculatum*.[4] An ointment or gel base is preferred so that as much of the active ingredient as possible is left in the site. It should be liberally and vigorously applied with a paint brush to insure that larvae in the depths of the wound are destroyed. To avoid reinfestation in extensive lesions or in bad seasons the treatment should be repeated twice weekly.

1594 1595

When large numbers of animals are affected and individual treatment is impractical, spraying with a 0.25% solution of coumaphos, chlorfenvinphos, or fenchlorphos, using a power sprayer, is recommended. The spray is directed forcibly into wounds and, except for

young calves, applied generally over the body to provide protection for about 2 weeks. Young calves may show signs of toxicity if sprayed too liberally and application should be restricted to the belly. These sprays can be used to protect animals which are not infested but are exposed to considerable risk or are to be shipped to free areas. In the latter situation dusts are also available if spraying is undesirable in cold weather. A pyrophyllite dust containing 5% coumaphos and 2% mineral oil is effective as a protectant if applied at the rate of 60–180 g per animal. Residual protection lasts for 3–7 days.

Thirteen acaricides, commonly used for *Boophilus microplus* control, have been tested against *Ch. bezziana* larvae. While they are not sufficiently active to use as a primary treatment, their continued use for tick control would reduce screwworm populations.

Ivermectin 200 mg/kg given subcutaneously kills all *Ch. bezziana* larvae up to 2 days old and many older larvae. It provides residual protection for 16–20 days. Bull calves treated with ivermectin at the time of castration were completely protected against strike.[5] A preliminary study showed that closantel at 15 mg/kg body weight was effective with a residual protection of 8–15 days.[6] Doramectin 200 mg/kg subcutaneously caused complete expulsion of *C. hominovorax* larvae within 8 days.[7] Prophylactic use of ivermectin and doramectin significantly reduced occurrence of screwworm strike in cattle.[8] Fipronil had a prophylactic effect, reducing occurrence of screwworm infestations in cattle and providing efficacious treatment in those that did become infested.[9]

28.4.2.10

CONTROL

The eradication of screwworm by genetic means, chemical control, trapping techniques and lures, and dispersal of flies has been reviewed.[10] In an enzootic area the incidence of the disease can be kept at a low level by the general institution of measures designed to break the life cycle of the fly. Surgical procedures should be postponed where possible until cold weather. In the warm months all wounds including shearing cuts must be immediately dressed with one of the preparations described under **treatment**. All range animals should be inspected twice weekly and affected animals treated promptly. Infestation of fresh navels is common and newborn animals should be treated prophylactically. If possible the breeding program should be arranged so that parturition occurs in the cool months. The routine use of ivermectin for internal parasite control provides protection for about 2 weeks.[5]

In the United States, the Caribbean, and central America an eradication program has been successfully carried out against *C. hominivorax* using the sterile insect technique (SIT). Huge numbers of pupae are mass reared on semi-artificial media and exposed to the sterilizing effects of cobalt 60. The resulting sterile male flies are released over large areas, primarily by aerially drops, where they compete with wild males for available females which mate only once. *C. hominivorax* has now been eliminated from the United States, the Caribbean, and all of Central America, up to the Darien Gap in Panama.[11] *C. hominivorax* appeared in Libya in 1988, apparently with a load of sheep transported from South America, but has been eradicated using sterile male flies from the USA.[12]

Attractants may also be used to reduce the fly population. A chemical bait has been developed, and when combined with an insecticide forms a screwworm adult suppression system (SWASS) which reduces the fly population and the incidence of strikes. An examination of the efficacy of various methods of baiting showed that polythene sachets containing sworm-lure 2, a pungent mixture of 11 chemicals, attracted flies (not *C. bezziana*) for at least 2 weeks and was as efficient as jar baits.[13] This result needs confirming in a screwworm endemic country.

28.4.3

WOHLFAHRTIOSIS (FLESH FLY)

Cutaneous infestation by larvae of the sarcophagid fly, *Wohlfahrtia magnifica*, has become a major disease of domestic livestock, including birds managed extensively (e.g. geese) in the Mediterranean basin, eastern Europe, and western regions of China.[1] The disease is particularly significant for sheep in these regions where it is more prevalent than strike by the calliphorid fly, *Lucilia sericata*.

Other species of this genus are known from North America, but they do not infest domestic species. They are predominantly reported from very young rodents and birds, although there are occasional reports from infants.[2] Mortality of infested hosts tends to be very high.

28.4.3.1

LIFE CYCLE AND EPIDEMIOLOGY

Larvae of this species are obligatory parasites developing only in the living flesh of warm-blooded vertebrates. They are not host specific. Adults are typical for this group of flies, being dark gray in color with three distinct black stripes on the thorax where the wings are attached.

Female flesh flies, which are active during the warm parts of the day, deposit first instar larvae on the host, usually in small groups of 15–20. Each female may produce up to 170 larvae. Completion of the three larval stages takes from 5 to 7 days after which the mature third instars leave the lesion and fall to the ground where they pupate. Development of the fly within the pupa is regulated by temperature and may require between 7 and 21 days.

Larvae are usually deposited near small wounds (bites of blood-feeding arthropods are sufficient to attract the larvae), but the favored sites appear to be the genitalia.[3] Irritation of the vulva associated with the use of vaginal sponges for estrus synchronization may be a predisposing factor in sheep.

Flies are active between April and October with several generations being produced. Little information is available on overwintering. Wildlife are suspected as being reservoir hosts, but little information is available on which are the most important.

28.4.3.2

PATHOGENESIS

Larvae have well developed mouthhooks which are used to abrade the skin surface and with the aid of a wide variety of salivary enzymes they quickly produce a dramatic lesion. 1595 1596

Lesions increase in size as the larvae grow and require additional fresh tissue. Each animal may have one or more focal lesions, each packed with larvae. In severe cases several lesions may coalesce into one larger site.

Animals are often struck multiple times during a season, suggesting the absence of protective immunity. This adds to the impact of this disease as animals must be constantly monitored.

28.4.3.3

CLINICAL PATHOLOGY AND NECROPSY FINDINGS

A clinical examination is all that is necessary to make the diagnosis. Larvae can be distinguished from those of the screwworm or the strike flies by the presence of a large posterior cavity surrounded by a number of prominent tubercles. However, specific identification should be done by a specialist. Larvae should be preserved in 70% ethanol.

Affected animals are clearly stressed, showing restlessness and anorexia.[3] Lesions formed at the vulva or prepuce are the most significant causing great discomfort and dysfunction. Lightly infested animals shown no impairment of productivity.[3] Infested animals develop strong antibody responses to salivary secretions, particularly of the third instars.[4]

28.4.3.4

TREATMENT

There are currently no products specifically registered for management of this disease. Evaluations of several drugs and treatment approaches have been made. Of particular interest is the equivocal results of trials with macrocyclic lactones. In sheep, ivermectin and moxidectin had no effect on existing infestations and no prophylactic effect[5] or only short protection against early instars.[6] In contrast, doramectin provided complete prophylactic protection for 21 days and significant reductions for 40 days.[7] The pyrethroid, cypermethrin, was less effective.[7]

The insect growth regulator dicyclanil has also been evaluated and shown to reduce prevalence of infestation in sheep.[3] The reduction not only occurred in treated animals, but was seen in untreated herdmates possibly as a result of the overall reduction in fly numbers.

28.5 ## Ked and louse infestations

Infestations with these insects cause irritation resulting in skin or wool damage. Blood loss may occur with some species.

28.5.1 ### SHEEP KED (*MELOPHAGUS OVINUS*)

This flat brown wingless fly, about 6–7 mm in length, was found in sheep throughout the world, but is now rarely reported in many countries. For example it wasn't mentioned in a review of livestock ectoparasites of Europe and the Mediterranean,[1] although anecdotal evidence suggests it may be present in isolated pockets associated with organic production.[2] In Australia it is now rarely seen. The ked may transmit *Trypanosoma melophagium* and *Rickettsia melophagi*, harmless blood parasites of the sheep. Staining of the wool by the feces of the ked reduces its value and gives it a peculiar musty odor. Heavy infestations cause skin blemishes which are costly to the leather industry. Sheep in poor condition suffer most from infestations. Goats may also be infested.

28.5.1.1 #### LIFE CYCLE

Keds live their entire life cycle on the host. Adults of both sexes are blood feeders and although the degrees of infestation usually encountered cause only irritation with resulting scratching, biting, and damage to the fleece, very heavy infestations may cause severe anemia. Spread is generally the result of direct contact between hosts. A recent review[2] suggests this exchange is primarily between dams and their offspring and that it is predominantly the newly emerged adults that migrate to new hosts. Larvae develop within the female one at a time and are deposited on the host as mature third instars which pupate within a few hours. The female ked lives for 4–5 months and may lay up to 10–15 larvae, so build-up of infection is slow. The larvae are attached to the wool fiber some distance above the skin and many larvae and pupae are removed at shearing. The young ked usually

emerges in 20–22 days but this period may be prolonged for up to 35 days in winter. The complete life cycle takes 5–6 weeks under optimal conditions. Heavy infestations usually occur in winter months and they decline in the summer. The parasite is mainly seen in colder, wetter areas and infestations may be lost when sheep are moved to hot dry districts. Resistance is acquired in time and resistant sheep grow better and produce more wool.

A seasonal pattern of infestation occurs. Keds are sensitive to hot, dry weather and numbers decrease markedly over the summer. Populations increase slowly over the autumn and winter. While keds that have been dislodged from the host can live for up to 2 weeks if in mild moist conditions, most die in 3–4 days and probably do not play a part in reinfesting sheep.

28.5.1.2

CONTROL

At shearing a large proportion of adults and pupae will be removed. This can provide effective control on adult sheep particularly where a combination of hot conditions and a short fleece will kill most of the remaining keds. However, some may remain alive in protected places such as the ventral neck and breech regions and on younger stock. If treatment is carried out within the next 2–4 weeks eradication will be achieved as long as all sheep are included and the insecticide used has a residual protection longer than the time taken for the last pupae to hatch.

Keds are particularly susceptible to organophosphates and most of those used to eliminate lice will also remove keds. They can also be used in higher dose rates in pour-on applications. Diazinon used as a pour-on removed all keds and prevented re-establishment for 9 weeks.[3] The synthetic pyrethroids are also active against keds; deltamethrin, cyhalothrin and cypermethrin are used. Cyfluthrin 2 mg/kg pour-on in sheep also eradicates ked and protects for 50 days. Amitraz will kill adult keds but has little residual action and is therefore usually combined with another compound to provide sufficient residual action to eliminate infections. Ivermectin given at the standard anthelmintic dose will also eliminate keds. Closantel which is mainly used against *Haemonchus* or *Fasciola* is effective against keds.

28.5.2 ## LOUSE INFESTATIONS (PEDICULOSIS)

Lice infestations are common throughout the world. The species are host-specific and are divided into biting and sucking lice.

28.5.2.1 ### Synopsis

28.5.2.1.1 #### Etiology

Species-specific sucking and chewing lice affecting all animals.

28.5.2.1.2 #### Epidemiology

Transmission from host to host. Lice show a marked seasonal periodicity rising from low numbers after summer to a peak in the following late spring. Foot lice infested from pasture.

28.5.2.1.3 #### Clinical signs

Irritation which causes rubbing, damage to the fleece or skin, and loss of milk production. Some species cause anemia. Foot lice cause stamping.

28.5.2.1.4 #### Clinical pathology

Hair loss may result from hypersensitivity.

28.5.2.1.5 #### Lesions

Skin lesions due to rubbing, fleeces have tufts protruding and lose their brightness.

28.5.2.1.6 #### Diagnostic confirmation

Lice can be seen on careful inspection. Preferred site varies with host and species of louse.

28.5.2.1.7 #### Differential diagnosis

In sheep must be differentiated from *Psorergates,* ked and *Psoroptes* infections. In other animals separate from allergic dermatitis.

28.5.2.1.8

Treatment

Organophosphates, synthetic pyrethroids and macrocyclic lactones.

28.5.2.1.9

Control

Pour-on and injectable treatments control lice on cattle, horses, sheep, and pigs. Good husbandry practices, will reduce infestations. Plunge or shower dips used on sheep, all sheep should be treated and sheep must be thoroughly wetted. Treatment should follow shearing which removes many lice; sheep in short wool are also easier to wet.

28.5.2.2

ETIOLOGY

The important species are:

- **Cattle:**

  Sucking lice – *Linognathus vituli* (long-nosed sucking louse), *Solenopotes capillatus* (small blue sucking louse), *Haematopinus eurysternus* (short-nosed sucking louse), *H. quadripertusus* (tail louse), *H. tuberculatus* (buffalo louse)

  Chewing lice – *Damalinia* (=*Bovicola*) *bovis*

- **Sheep:**

  Sucking lice – *Linognathus ovillus* (sucking face louse), *L. africanus, L. stenopsis* (sucking goat louse), *L. pedalis* (sucking foot louse)

  Chewing lice – *Damalinia ovis*

- **Goats:**

  Sucking lice – *Linognathus stenopsis* (sucking blue louse), *L. africanus*

  Chewing lice – *Damalinia caprae, D. limbata, D. crassiceps*

- **Pigs:**

  Sucking lice – *Haematopinus suis*

- **Horses:**

Sucking lice – *Haematopinus asini*

Chewing lice – *Damalinia equi*

28.5.2.3 LIFE CYCLE AND EPIDEMIOLOGY

28.5.2.3.1 Sucking lice

All life cycle stages are found on the host. Both sexes are obligate blood feeders, taking small meals from capillaries in the upper skin. Survival off the host is limited although some species, such as the foot lice of sheep, may survive away from the host for up to 2 weeks. Females lay 2–6 eggs per day which are attached to individual hair shafts. Eggs complete embryonation and hatch within 8–11 days of deposition. Lice have three nymphal stages, which bear a morphological similarity to the sexually mature adult stage. Each nymphal stage will take 2–4 days to complete. Louse development rate, at all stages, is highly temperature dependent and requires a narrow temperature range. Temperatures above 41°C and 46°C are lethal for eggs and adults, respectively, of *Linognathus vituli*. Optimal development takes place between 33°C and 37°C. Lice therefore show a seasonal periodicity with very low numbers in the summer when conditions are hot. Populations begin to increase with cooler fall temperatures, reaching maximum levels in late winter.

28.5.2.3.2 Chewing lice

All life cycle stages are found on the host. Lice feed on dead skin cells, hair, and oil secretions which they abrade from the surface using their chewing mouthparts. There may be some abrasion of the upper skin layers and there has been demonstration that sheep develop antibodies to salivary sections of *Damalinia* (=*Bovicola*) *bovis*.[1] Sex ratios are highly female biased and there are suggestions that parthenogenesis occurs in some species. Females deposit <1 egg per day. Embryonation is completed in 7–10 days producing nymphs which molt three times before reaching sexual maturity. As with the sucking lice development is highly regulated by temperature with a narrow range for optimal development and survival. Chewing lice can survive off the host for up to 2 weeks

Transmission of both types of lice occurs by direct contact but inert objects such as blankets, grooming tools and harness may remain infective for several days.[2] Sheep may

become infested with foot lice from the pasture. Young pigs may become infected some 10 hours after birth. Newborn calves also rapidly acquire infestations from their dams.

28.5.2.4

CLINICAL FINDINGS AND DIAGNOSIS

28.5.2.4.1

Sucking lice

All species cause irritation of the skin and stimulate scratching, rubbing and licking leading to restlessness, damage to hair coat or fleece and hides and loss of milk production. These behavioral changes[3] result in reduced efficiency, particularly in feedlot cattle.

Lice appear to be present on a large proportion of cattle,[4,5] but measurement of their impact on productivity has produced equivocal results. It is often believed that infestation has little or no effect on weight gains and hematological values.[6,7] However, there appears to be a synergistic effect between louse infestations and the presence of gastrointestinal nematodes that does have an impact on weight gain.[8] Anemia is rare but has been described for heavy infestations of *H. eurysternus*. Treatment, however, may be warranted to reduce the damage to hides and prevent damage to fences and other fixtures. Hairballs may be present in infested calves due to continual licking.

The pig louse spreads swinepox and while weight loss may not occur, even with heavy burdens, some pigs develop an allergic dermatitis and the consequent rubbing leads to skin lesions.

Foot lice of sheep are believed to live on blood. Light infestations may not cause clinical signs, but moderate to severe infestations cause stamping and biting the affected parts. Lice cause goats to rub or to bite their coat, which becomes matted and damaged. Angora goats can damage the hair shaft and lose their coats. Signs of infestation are restlessness, hair loss, and decreased milk production. In horses *H. asini* is the more serious species as it removes blood and may cause some anemia.

28.5.2.4.2

Chewing lice

Sheep body lice cause irritation and rubbing. The wool loses its brightness, becomes cotted and more yellow. There is evidence that a pelt defect called cockle is associated with infestation with body lice.[9] The quantity and quality of the fleece is reduced and losses up to AUS$3.20 per infested sheep have been measured.

Chewing lice on cattle also cause an increase in rubbing and licking which contributes to reduction of efficiency and damage to facilities. Hair loss has been attributed to this infestation, but it is a controversial association as many other causes are likely.

Diagnosis of lice on cattle and horses requires close visual inspection with particular attention being paid to known predilection sites.[10] These include the head, the sides of the neck, the dewlap, the escutcheon, and tail switch. Effective diagnosis requires that hair be parted and skin examined at several locations at each of the predilection sites. Use of a supplementary light source and restraint of the animal is very helpful.

Chewing lice of cattle, sheep, and horses are recognized by their rounded head and light brown color. These lice are highly mobile and will move away from inspection sites. Their eggs are difficult to see unless on dark haired cattle or horses. Sucking lice are recognized by their gray or blue-gray color and their pointed head. They tend to remain fixed to the skin.

Chewing lice may congregate on the dorsal surface and flanks, while sucking lice are found on the head and in the long hair of the mane and tail but, in heavy winter infestations, lice may be found on any part of the body. In sheep with long wool, greatest numbers of *D. ovis* may be seen on the midside, particularly the shoulders, from where they spread to the back and rump. After shearing, small residual infestations may be found on the ventral neck. Foot lice are usually found in clusters on those parts covered with hair, mainly on the lower limbs, but in heavy infestations they can be found in clusters above the hock, on the scrotum, in the belly wool, and more rarely on the face.

1597 1598

28.5.2.5

TREATMENT AND CONTROL

Self-grooming and grooming by headmates effectively regulates louse populations on most hosts, but the effectiveness is limited when hair coat or fleece become too long for the tongue surface to effectively remove the lice and eggs. Similarly, shearing is an important factor in reducing body lice populations on sheep. Between 30 and 50% of the population is removed with the fleece and those remaining are subjected to a more variable microclimate. Populations are at their lowest 30–60 days after shearing. Reversing temperature gradients as sheep move in and out of shade, and very wet conditions, will also reduce lice numbers.

Body lice of sheep are relatively easy to eradicate if a clean muster is achieved, if the sheep are thoroughly treated and reinfestation is avoided. However, in practice, failure to

eradicate commonly occurs due to the inability to thoroughly wet the fleece because of poor maintenance of dips or poor formulation of products, or because the lice are resistant to the chemical used. The most difficult problem when attempting to eradicate lice from flocks over a large area is the diagnosis of lice in lightly infested flocks. Dipping clean sheep is wasteful but if lightly infested flocks are not dipped the infestation will build up and may cause serious economic loss in the next year. Techniques have been devised to test for lice by digesting the wool and examining the residue for lice, but the delays inherent in such a system often mean that by the time the farmer obtains the results, the optimum time to treat sheep has passed. On-farm tests have been examined but none are yet sufficiently accurate.[11]

Affected sheep can be effectively treated in a plunge or shower dip with organophosphate insecticides (diazinon, coumaphos, chlorfenvinphos, carbophenothion, propetamphos), synthetic pyrethroids, or carbamates. The synthetic pyrethroids, cypermethrin and cyhalothrin, have been shown to be effective in sheep and give good residual protection. Products formulated as emulsifiable concentrates wet the fleece better and give better results than wettable powders.[12] Cypermethrin, alphamethrin, and deltamethrin are marketed as pour-ons for sheep and goats. They must be used immediately after shearing. A small proportion of sheep show irritation after application and some may show fleece damage. Further, most of the chemical that is applied remains in the tip of the fleece and grows out with the wool and so is not in contact with the lice.[13]

The spread of synthetic pyrethroid following backline treatment of sheep is slower than in cattle and horses and takes some days to reach maximum concentrations along the midside. However, the ease of application, low capital outlay required, and the need for only one muster has led to rapid acceptance of backline treatments. It is important that the pour-on is applied along the spine from the poll to the tail. Failures to eradicate occur if the sheep are not cleanly shorn, and in large-bodied sheep with extensive neck folds which are difficult to shear cleanly. The presence of unshorn lambs, cotted or *Dermatophilus*-affected fleeces, wrinkly sheep or inexpert shearers make backline pour-on application an inappropriate method. Heavy rain following application may also cause failure. Some lice remain alive for up to 6 weeks after backline treatment and so sheep are infective for this time. Jetting races have been used to treat sheep because of their ease of use and the speed with which sheep can be treated. However none of the machines marketed in Australia is able to eradicate lice even from sheep with short wool.[14]

The manufacturer's recommendations should be accurately followed, particularly when using shower dips. The most common cause of failure when using shower dips is poor maintenance of the pump so that insufficient volume of dip wash is applied from the overhead sprays. Blocked jets, incorrect speed of rotation of the top spray and leaving sheep in the shower for insufficient time are also common faults.

Infested long-woolled sheep can be jetted to reduce the population until the sheep can be shorn and dipped. Treatment of sheep in long wool leads to residue problems in the wool presented for sale. Every effort should be made to treat sheep properly in the first 2 weeks after shearing to insure eradication of lice and to present wool without insecticidal residues. Cyhalothrin has been shown to eradicate body lice from long-woolled sheep when applied by jetting at 20 ppm, but in field use eradication is rarely achieved. Phoxim 125 mg/L has also been reported to eliminate lice in long-woolled sheep, while 250 mg/L gave at least 4 months of protection against reinfestation. An ivermectin 0.03% jetting fluid was reported to have high efficacy in treating lice in sheep with 3–9 months wool, but failed to eradicate. High concentrations of cyhalothrin (1500 ppm) and diazinon (36000 ppm) in 100 mL applied to sheep has also proved effective but requires a practical method of application. No treatment is known that can eradicate lice from long-woolled sheep under field conditions. Following treatment of foot lice, sheep should be moved to a paddock that has been free of sheep for a month.

Treatment of goats has not been studied extensively and the treatments used on sheep and cattle are thought to be effective in goats. Lactating goats should not be treated.

Organophosphates (e.g. fenthion, famphur, chlorpyrifos, temephos, methidathion, fenchlorphos, phosmet) and pyrethroids (e.g. deltamethrin and flumethrin) have been used in pour-on application on cattle.[12,13] While pour-on applications are easy to use, none will kill all lice; they are expensive compared with sprays if large numbers are to be treated, and in many countries they should not be used on lactating cows. Similarly, organophsphates (diazinon, coumaphos, ethion) and pyrethroids (cypermethrin) or combinations (bromophos-ethyl combined with chlorfenvinphos) are used as sprays or dips for cattle. Macrocyclic lactone based products (ivermectin, moxidectin, doramectin and eprinomectin) are available as pour-on or injectable formulations for cattle and have shown excellent efficacy against both sucking and chewing lice. Persistence of activity is one of the exceptional benefits of these products.[14,15]

Fenthion 2% has been widely used on horses in Australia with good results although coat color changes and, rarely, hair loss does occur. A single subcutaneous injection of 0.2 mg/kg ivermectin will remove sucking lice but is not completely effective against chewing lice. Moxidectin, a compound with ivermectin-like activity, performs similarly.[12] Treatment of horses with a shampoo containing 1% selenium sulfide three times at 10 day intervals eradicated lice; most horses showed a marked improvement after treatment.[13]

Sheep lice have been shown to quickly develop insecticide resistance and strains of *D. ovis* which are resistant to the chlorinated hydrocarbon insecticides are common in the United Kingdom, while strains of lice resistant to the synthetic pyrethroids have followed inappropriate backline use of these compounds.[14] Resistance management strategies that involve rotational use of the various insecticide/parasiticide active ingredient categories should be adopted wherever practical. For example, if pyrethroid-resistant lice are present an organophosphate or macrocyclic based product should be used. Subsequent treatments should involve another change of compound class.

Treatments should be timed to coincide with the beginning of population growth (i.e. autumn or early winter). Extremely early treatments often result in spring outbreaks that result from very small residual populations on a few animals. When products with short residual activity are used (e.g. organophosphates) two treatments separated by 10–14 days are required. The second treatment will kill any newly hatched nymphs. Products with persistent activity in excess of 21 days (e.g. macrocyclic lactones) do not require a second application.

1598 1599

Effective management of lice in a herd requires that new animals be isolated for a period of time sufficient for all lice to be eliminated by treatment. The introduction of one or two lousy sheep to a flock, such as occurs when stray infested sheep enter a clean mob, leads to a slow build-up of infestation.

28.6 ## Tick infestations

28.6.1 ### Synopsis

28.6.1.1 #### Etiology

Many species of ticks act as vectors of disease or cause death from anemia; others cause paralysis. Heavy burdens cause loss of production.

28.6.1.2 #### Epidemiology

Life cycles vary widely both in the number of hosts required and the host specificity. Animals are infested by larval or nymphal states on the ground.

28.6.1.3 #### Clinical signs

Anemia, paralysis, tick fever, and tick worry.

28.6.1.4 #### Clinical pathology

Ticks obvious on clinical examination. Blood smears for tick fevers (*Babesia, Theileria*, and *Anaplasma*).

28.6.1.5

Lesions

Skin damage due to biting and rubbing, anemia. See other chapters for lesions due to diseases transmitted by ticks.

28.6.1.6

Diagnostic confirmation

Ticks easily found, should be identified to species.

28.6.1.7

Treatment

Dipping, pour-ons and injectable acaricides.

28.6.1.8

Control

Regular treatment at intervals dependent on the life-cycle of the tick, pasture spelling to destroy free-living stages, the use of resistant cattle and vaccination all play a part.

Tick infestations are of great importance in the production of animal diseases. In addition to their role as vectors of infectious diseases, as outlined below, heavy infestations can cause direct losses. Many are active blood feeders and may cause death from anemia. Some species cause tick paralysis and it is possible that other ticks may elaborate toxins other than those causing paralysis.[1] Heavy tick burdens cause sufficient irritation and stress such that affected animals become anorexic which may lead reduced productivity. One tick, *Boophilus microplus*, is reported to affect in excess of 75% of the world cattle population.[2] The economic impact has been estimated at $7 (US) per animal per year and in Brazil with the fifth largest cattle herd, the losses are estimated at $2billion per year.[3]

The life cycles of the ticks vary widely. Some species pass their entire life on the one host, others pass different stages of the cycle on successive hosts, and others are parasitic only at certain stages. The eggs are laid in the soil and larvae attach themselves to a passing host on which they may develop through one or more nymphal stages before becoming adults. Adult females engorge on blood or lymph and drop to the ground to lay their eggs. One-host ticks are more easily controlled than those which pass part of their life cycles away from the host. A list of the single and multiple host ticks is shown in Table 28.1.

Although many ticks favor a particular host they are usually not completely host-specific and many parasitize a wide variety of animals. In the limited space available here the species are

listed according to whether they cause worry only or transmit infectious diseases of large domestic animals.

For more detailed information on transmission of infectious diseases and the biology and distribution of ticks the papers by Neitz[4] and Theiler[1] should be consulted, while the role of ticks in disease is covered well by Sonenshine.[5]

28.6.2 Ticks causing paralysis

Paralysis is not uncommon in young domestic animals which are heavily infested with ticks. A review lists 31 species in seven genera of ixodid ticks and seven species in three genera of argasid ticks as being implicated in tick paralysis.[6] The most important species are given in Table 28.2. Details of the clinical syndromes are provided in Chapter 32. Recovery is usual in early[7] mild cases if the ticks are removed but antiserum against some (e.g. *Ixodes holocyclus*) is available.

Table 28.1 Single and multiple host ticks

One-host ticks
Boophilus spp.
Margaropus winthemia
Otobius megnini (adults are not parasitic)
Dermacentor albipictus
Two-host ticks
Rhipicephalus evertsi
R. bursa
Hyalomma spp. (most have two or three hosts)
Three-host ticks
Ixodes spp.
Rhipicephalus spp. (except *R. evertsi* and *R. bursa*)
Haemaphysalis spp.
Amblyomma spp.
Hyalomma spp. (most have two or three hosts)
Ornithodorus spp. — many hosts
Dermacentor spp.

28.6.3

Ticks which transmit protozoan diseases

Ticks are the most important vectors of many protozoan diseases, the protozoan in most instances surviving from generation to generation of ticks by infecting their eggs. Where control of these diseases is to be undertaken it is necessary to know which ticks are vectors, how many hosts the tick parasitizes during a life cycle and which animals can act as host. Much of the information on these points is fragmentary and only a summary is presented in Table 28.3.

28.6.4

Bacterial, viral and rickettsial diseases transmitted by ticks

1599

1600

The transmission of diseases associated with these agents may be effected by means other than ticks. *Anaplasma marginale* can be spread by biting flies if large numbers are present when the animals are experiencing a heavy parasitemia. Outbreaks of anaplasmosis can also occur following the use of unclean instruments for dehorning, vaccination, castration or blood sampling, and is easily caused by blood transfusions. The ticks involved more commonly in transmitting bacteria, viruses, and rickettsia are given in Table 28.4. Transmission of *Anaplasma* may be transovarially, one stage becoming infected and a subsequent stage passing the infection to a new host, or ticks may transmit infection within the one stage if they detach and feed on a new host.

Table 28.2 Ticks reported to cause paralysis

Animal	Tick	Country
Sheep, calves, goats	*Dermacentor andersoni*	United States, Canada
	D. occidentalis	United States

28.6.5

Ticks which cause direct losses

Ticks cause damage to hides and loss of production, anemia and death when they are present in large numbers. They also cause greater morbidity and mortality during periods of drought, as well as delays in fattening resulting in animals held longer before they can be sold. A list of ticks which have this effect on production but which are not known to cause paralysis or transmit infectious diseases in farm animals, is given below.

- *Otobius megnini* – the ‘spinose ear tick’ of the United States and Canada
- *Amblyomma americanum* – the ‘Lone Star tick’ of the United States
- *A. maculatum,* – the ‘Gulf Coast tick’ of the United States
- *Margaropus winthemi* – of South America and Africa
- *Ornithodorus moubata* – of Africa and southeast Asia
- *O. savignyi* – of Africa and southeast Asia

- *Haemaphysalis longicornis* – of Australia and New Zealand.

28.6.6 TREATMENT AND CONTROL OF TICK INFESTATIONS

Four methods are now available to control ticks:

- Treating with acaricidal agents
- Pasture spelling
- Vaccination
- Use of resistant cattle.

Crude vaccines made from extracts of semi-engorged adult female *B. microplus* give effective immunity. Antibody destroys cells lining the tick's gut and allows blood to escape into the hemocele, some ticks die and the fertility of those remaining is reduced by up to 70%. The fertility of males is also reduced.[7] A recombinant vaccine based on a membrane bound glycoprotein Bm86 has been isolated and shown to be as effective as the native antigen, and to be effective against acaricidal resistant ticks.[8] Its major effect is a progressive control in tick numbers in successive generations through a decrease in their reproductive capacity.[9] Because the vaccine acts against an antigen in the tick's gut to which cattle are never exposed, they must be given booster injections at regular intervals.

This was the first recombinant parasite vaccine sold commercially and is marketed in Australia as Tickgard. A similar product, using the same antigen produced in a eukaryotic expression system, was produced in Cuba and has been trialed in other countries.[10] A second antigen has now been added to the vaccine (Tickgard 2). This significantly enhances efficacy and does not impair the response to Bm86. Addition of a saponin adjuvant has greatly increased the efficacy of the vaccine.[2]

Although vaccines offer long term control, they need to be used with pasture management, dips and tick resistant cattle as part of an integrated pest management control system. Certain *Stylosanthes* spp., tropical legumes, can kill or immobilize larval ticks and the use of these plants may simultaneously improve pasture quality and reduce the pasture contamination of larval ticks if high legume to grass ratios are achieved. *Brachiaria brizantha* has also been shown to be lethal to *Boophilus* larvae.[11]

Table 28.4 Diseases associated with bacteria, viruses, and rickettsia and reported to be transmitted by ticks[22]

Disease	Causative agent	Vector ticks	Country
Tick pyemia (lambs)	*Staphylococcus aureus*	*Ixodes ricinus*	Great Britain
Tularemia (sheep)	*F. tularense*	*Haemaphysalis leporispalustris, H. otophila, Dermacentor andersoni, D. variabilis, D. pictus, D. marginatus, Ixodes luguri*	United States
			Norway, Europe, Russia, and states of the former USSR
Anaplasmosis			
Cattle	*Anaplasma marginale*	*Boophilus annulatus, Argas persicus, Dermacentor albipictus, D. andersoni, D. occidentalis, D. variabilis, Ixodes scapularis, Rhipicephalus sanguineus*	North America.
		Boophilus microplus	Australia and S. America
		B. decoloratus, Hyalomma excavatum, Rhipicephalus bursa, R. simus,	Africa
		Haemaphysalis punctata, Ixodes ricinus	Europe
		Boophilus (annulatus) calcaratus	Russia, and states of the former USSR
Sheep and goats	*Anaplasma ovis*	*Dermacentor silvarum, Rhipicephalus bursa, Ornithodorus lahorensis*	Russia, and states of the former USSR
Brucellosis	*Brucella abortus* and *Br. melitensis*	Many ticks may be infected but infection of host appears to occur only if ticks or their feces are eaten	Russia, and states of the former USSR
Heartwater	*Ehrlichia ruminantium*	*Amblyomma* spp.	Africa and Caribbean
African swine fever	Virus	*Ornithodous* spp.	Africa, Spain, Portugal
Louping-ill	Virus	*Rhipicephalus appendiculatus* (lab only)	Africa

		Ixodes ricinus	England
Tick-borne fever	*Anaplasma phagocytophila*	*I. ricinus*	Great Britain, Norway
		Rhipicephalus haemaphysaloides	India
Caseous lymphadenitis of sheep	*Corynebacterium pseudotuberculosis*	*Dermacentor albipictus*	North America
Epizootic bovine abortion	*Spirochete*	*Ornithodorus coriaceus*	United States
Nairobi sheep disease	Virus	*Rhipicephalus appendiculatus*	Africa
Lyme disease	*Borrelia burgdorferi*	*Ixodes dammini, I. pacifieus, I. rieini*	United States, Europe, Australia

Integrated management of ticks requires the use of several complementary approaches to reduce populations below acceptable thresholds. One component of these strategies is the development of acaricidal pathogens that may augment other approaches such as vaccination and selective acaricide application. Fungal pathogens are under evaluation for use in this type of program, in particular *Metarhizium anisopliae* and *Beauvaria bassiana*.[12,13]

28.6.6.1

Choice of acaricide

Individual animals can be effectively treated by the application of any one of a number of acaricides applied either as a spray or by dipping. The choice of acaricide depends largely on three factors:

- The persistence of the compound on the skin and hair coat
- The likelihood of residues toxic to man appearing in the milk or meat
- Whether or not the ticks in the area have developed resistance to the particular acaricide.

The same criteria apply in control as in treatment except that cost becomes a limiting factor when large numbers of animals require frequent treatments and it is obvious in some circumstances that the effect of tick infestation on Brahman-cross steers is insufficiently great to warrant treatment. It is impossible to make specific recommendations on methods of application and the most efficient insecticide to use because these vary widely between species of ticks. However, whenever possible, treatment should be given systematically in

a program based on the life cycle and epidemiology of the tick. A number of treatments may be used early in the tick season to prevent the increase in tick numbers. Care must be taken in areas where tick fevers also occur, not to disrupt the transmission of the tick fever organisms and leave the cattle susceptible to later infection.

Amitraz, a formamidine, and the synthetic pyrethroids have been used widely in Australia and have proved to be efficient, active against organophosphate resistant strains and safe. In a study in the USA 0.025% amitraz applied as a whole body spray or by dipping gave 86.0–99.8% control respectively.[14] Ticks resistant to DDT are also resistant to the synthetic pyrethroids, and to overcome this the pyrethroids can be combined with an organophosphate. Successful combinations in Australia are cypermethrin plus chlorfenvinphos and deltamethrin plus ethion. A synthetic pyrethroid, flumethrin, has been marketed by itself at higher use concentrations for both plunge dipping and as a pour-on treatment. As a 1% pour-on 1 mL per 10 kg body weight gave 97% efficacy while 0.0033% as a spray gave 99% and acted more quickly.[15] The efficacy of synthetic pyrethroid impregnated eartags has been reported but these are likely to lead to resistance. Cyhalothrin also controls multiresistant strains and is used in plunge dips.

Bioassay results show lambdacyhalothrin to be as effective as cyhalothrin as a whole body spray, although the 1% pour-on was less than 50% effective.[16] Resistance to all pyrethroids has been reported.[17] Three pyrethroid acaricides have been shown to markedly reduce the hatching of eggs. Permethrin 0.1% or cypermethrin and cyfluthrin 0.05% could be useful in cleansing and disinfecting premises.[18]

The organophosphates as a group are effective but strains resistant to many of them have appeared. Other drugs in current use include dioxathion, diazinon, carbophenothion, coumaphos, ethion, bromophos-ethyl, chlorpyrifos, and phosmet. Pour-on applications of chlorpyrifos and phosmet have been tested but were not as effective as spray applications. Addition of acaricides to the feed has also been tried but has not been successful, while eartags impregnated with tetrachlorvinphos did not give satisfactory control and increased the risk of resistance developing to the drug.[19] Ivermectin given subcutaneously gives satisfactory control of *Boophilus microplus* for 21 days following an initial lag period of 2 days. As little as 0.015 mg/kg per day gives complete control and raises the possibility of a slow-release subcutaneous implant. Two treatments of 0.2 mg/kg at 4-day intervals is considered satisfactory in cleansing cattle under field conditions.[20] However, ivermectin may not be effective against *Ixodes ricinus*[21] but a slow release bolus active for 90 days

1601
1602

did give good control of a variety of ticks.[19] If given topically 0.5 mg/kg was required to give the efficiency achieved by 0.2 mg/kg subcutaneously.[22]

Moxidectin 200 mg/kg subcutaneously at 4-week intervals or 500 mg/kg as a pour-on along the back gives good protection against *B. microplus* resistant to organophosphorous insecticides and DDT, and each treatment gave a rapid knockdown effect on populations of buffalo fly after treatment.[23] Doramectin 200 mg/kg is highly efficacious in removing *B. microplus* and preventing re-establishment.[24] Closantel 22.2 mg/kg orally to cattle disrupted the life cycle of *Rhipicephalus appendiculatus*; those that oviposited laid few eggs and most of these did not hatch. Few larvae or nymphs molted.[25]

Ticks in the ear of horses should be treated by the insertion of a few drops of an oily acaricidal preparation.

Preparations vary in the duration of the protection they afford and local conditions of rainfall and tick population must be taken into account when determining the time intervals between sprayings or dippings. A special case is that of young lambs which are exposed to tick pyemia. Sprays, dips, and ointments are too toxic and the most effective procedure is the application of a liquid emulsion cream containing the insecticide to the wool-less parts of the body. Chlorpyrifos 0.48 kg/ha markedly reduces the number of ticks on the pasture, but is too expensive for routine use.

Resistance to chemical acaricides has become a major issue for the effective management of one cattle tick, *Boophilus microplus*. In many cases cross-resistance between chemical families occurs, further complicating the use of rotational scheme aimed at managing the development and degree of resistance. The development of strains of this tick resistant to macrocylic lactone has been reported.[26]

28.6.7 CONTROL AND ERADICATION

In most countries all that is attempted is reduction of the tick population by periodic dipping or spraying. Complete eradication is extremely difficult because of the persistence of ticks, especially multihost ticks, on wild fauna, and the ability of adult ticks to live for very long periods away from a host. On the other hand, continuous treatment to restrain the tick population is highly conducive to the development of resistance, a problem which has become apparent in many tick areas. *Boophilus annulatus* was eradicated from the southeastern United States by a program of continuous dipping at short intervals of all livestock in the area. *B. microplus* was also eradicated from Florida by a similar procedure

but 20000 deer, the important alternate host in the area, had to be slaughtered. Concern has been expressed that deer and other wildlife species may threaten efforts to prevent *B. microplus* and *B. annulatus* becoming re-established in southern USA after they are introduced from Mexico.[27] Attempts to eradicate other single-host ticks in other countries have not been generally successful.

Although both dipping and spraying are recommended for the control of ticks, complete wetting of the animals, which can only be effected by dipping, is essential if eradication is to be undertaken. This adds another impediment to eradication plans because of the cost of constructing proper dips and yards. When one considers that dipping may have to be carried out every 14 days for 15 months, that every animal in the eradication area must be dipped, and that a strict quarantine of the area must be maintained, it is obvious that eradication cannot be undertaken lightly. The use of pour-on applications, which allow a longer period between treatments, and of ivermectin, will necessitate a review of control and eradication techniques.

Measures other than the application of insecticides used in the control of tick infestation include burning of pasture, removal of native fauna, plowing of fields, and rotational grazing. So little is known of the bionomics of specific ticks in specific areas that these measures have been largely unsuccessful and it is impossible to provide details for their proper implementation.[1]

In those areas where the epidemiology is known it has been shown that in regions with a cold winter the females stop laying eggs, and that the development of eggs is prolonged. This results in few larvae being available in the spring, and if repeated treatments are given at this time, pasture contamination will remain low for some months. In hot tropical areas where the required temperatures for tick breeding are always present, the dry period may cause mortality by desiccation.

Pasture spelling and rotational grazing have been shown to be capable of greatly reducing the tick population on farms in some areas. If cattle are placed on spelled pastures early in winter when the ticks are producing few or no progeny and then alternated at 4-monthly intervals, the tick population can be controlled with a markedly lower number of treatments. The practicability of the procedure depends upon a full-scale financial assessment of the increased weight gains relative to the costs of management. Duration of the spelling period varies between 2 and 3 months in summer to 3–4 months in the winter, but these intervals need to be determined for each district. In practice, pasture spelling is rarely used.

It is possible to reduce the impact of ticks and tick-borne diseases by the introduction of Brahman and Brahman-cross cattle which are more resistant than British breeds. The resistance has been shown to be largely acquired, and is mainly expressed against the larvae in the first 24 hours after attachment.[28] In Australia the possibility that *B. microplus* might escape from its control area because of increased resistance to acaricides has been realized. For this reason a great deal of attention is being paid to the possibility of selecting cattle for tick resistance. In most tick-infested areas, cattle should have up to 50% *Bovis indicus* breeding, as this allows a reduction in the frequency of treatments. Penalties such as reduced liveweight gains, late maturity and poor temperament become evident when cattle have more than 50% *B. indicus*. With successive infestations cattle differ in their response to *Boophilus microplus*. Thus there is increased irritation and more licking[28] and a decrease in the number of ticks carried. Resistance to ticks has been shown to be heritable[29] and can be increased by breeding from cows and bulls selected for resistance. Selection for tick resistance does not affect milk production.[30]

Other special cases include *Otobius megnini*, the nymphs of which drop off to molt and lay eggs in protected spots, necessitating the spraying of buildings, fence posts, feed troughs, and tree trunks in feedlots where heavy infestations are most common. *Ornithodorus* spp. ticks are difficult to control because the nymphs and adults attach to feed for brief periods only. Where ticks which cause paralysis are common it may be necessary to apply an insecticide as a dust and dip at short intervals.

28.7 Miscellaneous flies, midges, and mosquitoes

Although these insects differ quite markedly they are dealt with together because they exert similar deleterious effects. Their activity causes stress and induces behavioral changes and in many cases are important vectors for a variety of parasites and infectious diseases.

28.7.1 STABLE FLIES

The stable fly, *Stomoxys calcitrans*, has a cosmopolitan distribution, occurring in most countries. Other species, including *S. nigra*, occur in South Africa. *S. calcitrans* is about the size of a house fly, is gray in color. These flies are the most economically important species affecting confined livestock in North America. Flies rest on fences and structural surfaces in a characteristic head upwards position and can readily be recognized by the prominent, forward-directed, pointed proboscis between short palps. Stable flies of both sexes are blood feeders, attacking particularly horses, cattle, to a lesser extent pigs and people. Bites are quite painful and often bleed freely when fresh. The flies are intermittent feeders, spending only short periods on the host, while most of their time is spent resting on fences and building sides. Eggs are laid in high moisture areas of rotting hay or straw, along the edge of silage pits, on the edges of manure pack of feedlots and compost piles. Mature larvae leave the high moisture sites to pupate in drier sites nearby. Development times are regulated by temperature, with higher temperatures resulting in more rapid development. A complete life cycle will require 3–4 weeks in summer. In termperate climates flies exhibit a distinct seasonality with peak populations in mid to late summer.[1] Larvae will overwinter in warmer areas of silage piles. The flies are highly mobile traveling up to 20 km in search of suitable hosts.

Feeding activity by the flies results in stress to the animals and reduced efficiency through reductions in feeding time. When large numbers of flies are present the animals will bunch to reduce biting rates. At high temperatures the bunching may result in cattle overheating. A localized sensitivity of the forelimbs of cattle may develop and result in the formation of intradermal blisters which coalesce to form bleeding sores. With very heavy infestations some deaths may occur. Populations can be assessed by counting the number of flies on the front legs of cattle. When the average number exceeds 5–10 per animal significant losses are occurring and population management is required.

Stomoxys calcitrans are mechanical vectors for anthrax, infectious equine anemia, bovine virus, diarrhea virus, and surra. They are intermediate hosts for the nematode *Habronema majus* which is reputed to be a cause of allergic dermatitis in horses in Japan.

Effective management of stable flies requires removal of high moisture, rotting organic matter from the environment.[2] Edges of silage pits, manure, and compost piles should be kept dry and manure-contaminated bedding should be removed regularly. Insecticide treatments must be applied to all exterior surfaces (i.e. barn sides, fences, and exterior of feed bunks). Diflubenzuron 0.5 g/m^2 sprayed in a cow barn completely inhibited breeding of the house fly and stable fly.[3] Spraying of fixtures and walls, particularly sunlit walls where the flies often remain unnoticed, with long-acting compounds such as tetrachlorvinphos, diazinon, crotoxyphos, and propoxur reduces infestations for 2 weeks or longer.

Application of insecticides or repellants directly on animals is generally impractical because of the short duration of efficacy. Low frequency of insecticidal application, when necessary, slows the development of insecticide resistance. Crotoxyphos and methoxychlor can also be sprayed onto cattle giving about 4 days of protection. Fenchlorphos can be used but requires daily spraying or daily or alternate daily wipe-on application for good control. Permethrin applied as a microencapsulated formulation gave longer protection than an emulsifiable concentrate.[4] Affected horses can be treated locally with an analgesic cream, and if the irritation is severe they can be tranquilized with acetylpromazine.

28.7.2

HORSE FLIES; MARCH FLIES OR BREEZE FLIES (*TABANUS* SPP.); DEER FLIES (*CHRYSOPS, HAEMATOPOTA,* AND *PANGONIA* SPP.)

These large, robust blood feeding flies are widespread in both temperate and tropical regions. Only the females take blood meals, but the bites are savage and cause significant distress to large animals, particularly horses and cattle. These flies can act as mechanical vectors of diseases associated with viruses (equine infectious anemia, bovine leukosis, vesicular stomatitis, hog cholera), bacteria (anthrax, tularemia), and trypanosomes (surra). Eggs are laid on the leaves of plants growing in or near standing water. The larval and pupal stages occur in the water or mud and the life cycle takes 4–5 months to complete. The flies are active in summer and attack animals principally on the legs and ventral abdomen. Duration of activity can be relative short (i.e. 3–4 weeks), but stress on the animals can be very high during that time. Fly attacks lead to bunching of animals[5] with the attendant likelihood of overheating and in some cases resulting in animals stampeding through fences. Control is

difficult unless wet areas can be drained or livestock kept away from these areas where the flies are most active. Repellents have been used and are reasonably effective in horses subject to fly-worry. The use of *o*-diethyl toluamide (DEET) affords protection for only a few days and is costly, but its use in milking cattle gives increased milk yield and butter fat. Permethrin, a synthetic pyrethroid, used as a spray or as a dust on cattle and horses, killed 90% of flies for about 2 weeks after treatment. Synthetic pyrethroid impregnated ear tags give very little protection against these flies.

28.7.3

BUFFALO FLIES; HORN FLIES (*HAEMATOBIA* SPP.)

These small (6 mm) grayish flies have distinct geographical distributions, *H. irritans exigua* in Australia and South-east Asia, *H. irritans irritans* throughout North and South America and Hawaii, and *H. minuta* in Africa. *Haematobia irritans irritans* is common in Europe where it causes few problems This species was transported to North America in the late 1800s, where it rapidly established and spread. It has subsequently moved into South America where it has also become a major problem. They have similar life cycles and habits. Both sexes of these flies are obligate blood feeders, primarily attacking pastured cattle and water buffalo. They do not survive off the host, other than for short periods. They are not known as vectors for any disease agents other than the nematodes *Stephanofilaria* spp. They cause significant reductions in productivity of pastured cattle through induction of stress, changes in grazing patterns and, in extreme cases, blood loss. Burdens of 200–500 flies will reduce weight gains of beef cattle (up to 14% reduction)[6] and milk yield of dairy cows. Heavy infestations (over 1000 flies) can cause serious loss of condition and rarely, deaths. Control results in higher feed efficiency, increased growth rate and increased calf weaning weights.

1603 1604

The flies congregate chiefly on the withers, shoulders and flanks as well as around the horns and eyes. Flies take numerous (15–20) small blood meals per day. In North America feeding often takes place on the ventral midline and several 2–5 cm diameter feeding lesions are often observed. Zebu cattle are less affected by the flies than British breeds and although they may carry large populations of flies, they show fewer feeding lesions.

The flies are easily recognized by the way in which the wings are held at rest, slightly divergent and angled upwards away from the body. Adult flies stay on the host most of the time, unless disturbed. Females leave the host, as feces are passed, to deposit eggs around edges of the freshly deposited dung. Larvae develop within the dung pat, feeding primarily on bacteria. Development is regulated by environmental temperatures and the larvae are

stimulated to enter diapause (arrested development) if temperatures become too low.[7] Mature larvae exit the dung to pupate in the dry soil below and around the pat. A complete life cycle may require up to 3 weeks under optimal environmental conditions. Thus, at higher temperatures in excess of 15 generations may be produced in a single season. In more temperate climates such as Canada and the upper United States, only five generations may occur.

While adults rarely leave the host except for oviposition the newly emerged flies of *H. irritans irritans* will travel up to 20 km in search of new hosts. They may be dispersed also by prevailing strong winds, and they are carried long distances by the movement of cattle to new pastures. The distribution of *H. irritans exigua* is controlled by environmental factors, particularly temperature and humidity. Below 21°C (70°F) the flies become sluggish and at 5°C (41°F) they become comatose.

Infestations have been controlled by traps, insecticide sprays, back rubbers, dust bags, or eartags impregnated with insecticides. Traps have been designed for use with dairy cattle that walk through them on their way to and from the dairy. The flies, dislodged by gauze strips, are retained in the trap and killed when they rest on the insecticide-coated walls. Traps are rarely used today but recent work with modified traps has given 80–90% control.[8]

Back rubbers consist of absorbent material, impregnated with insecticide or oil, wrapped around a cable or chain suspended from a central pole and attached to ground level supports or as a cable suspended a little over a meter above the ground between two posts 4–5 m apart. Cattle quickly learn to use rubbers to dislodge flies and their coats become smeared with insecticide. Ethion 1% in fuel oil is commonly used against *H. irritans exigua* while coumaphos 1 or 2% has been shown to be effective against horn flies. Insecticide-impregnated eartags attached to back rubbers and dust bags controlled horn fly for about 6 weeks, while fenvalerate tags were still effective 18 weeks after application.[9]

Eartags impregnated with organophosphorus compounds and synthetic pyrethroids have been widely used, but resistance has built up to levels that make this technique ineffective.[10] Discontinuing the use of pyrethroid impregnated ear-tags for one season does not allow substantial reduction in resistance to occur.[9] Recent work reported that ear-tags impregnated with 20% diazinon gave 90–100% control of *H. irritans exigua* in dairy and beef herds and allowed better weight gains,[11] but if continued will lead to resistance as resistance to diazinon has been reported in eastern Canada and in the United States. Eartags impregnated with compounds of both classes have been effective in managing increases in pyrethroid

resistance. Current recommendations for use of impregnated eartags note that tags should be applied to the cows (because they harbor the most flies and present the largest surface area for exposure to the insecticide) at the maximum recommended rate. While this is less convenient it helps to avoid one of the leading causes of insecticide resistance which is the dilution of the insecticide as it spreads from calves to cows. Flies can also be controlled by dipping, but this technique is rarely used solely for flies. Organophosphorus compounds have a residual protection of only a few days and products are combined with synthetic pyrethroids to extend the protective period. In areas where cattle ticks require regular treatment adequate control of flies may be gained incidentally, but if treatments are not effective cattle can be oversprayed with pyrethroids.

Macrocyclic lactone endectocides are highly effective against larval horn flies,[12] as well as larvae of face flies, stable flies, and house flies, often killing larvae for periods in excess of 8 weeks. However, in terms of practical control, where flies immigrate from surrounding herds, the duration of efficacy is not more the 2 weeks.[13] In addition, the macrocyclic lactones generally cause significant reductions of non-target insects in the dung community, many of which are beneficial as they are natural enemies of the horn fly and buffalo fly.[13] The various macrocyclic lactone products have differential effects on flies and other dung insects and it appears that moxidectin has the least impact.[14]

Pour-on formulations of pyrethroids are highly effective as evidenced by application of 1% cyfluthrin.[15] Insect growth regulators (e.g. Diflubenzuron) applied as a bolus give 80% control of the immature stages of the face fly-horn fly in the manure for at least 20 weeks but reduced the number of dung beetles for 7 weeks. A 3% methoprene bolus was also active against flies but had no apparent effect on the dung beetles.[16]

28.7.4 HORSE LOUSE FLIES (*HIPPOBOSCA EQUINA*, *H. RUFIPES*, AND *H. MACULATA*)

The horse louse fly, *Hippobosca equina*, is a common parasite of horses and cattle in many tropical countries. It is a flat, glossy, reddish-brown fly, slightly bigger than a housefly. These flies are blood feeders and live most of the time on the host, particularly on the perineum and between the hindlegs. Female flies deposit single mature third instars which pupate in dry humus; the puparia mature to adult flies. The flies appear to cause little annoyance in horses which are accustomed to them but horses experiencing them for the first time manifest fright and irritation. Being blood feeders they may act as mechanical vectors for infectious diseases. Topical spraying of susceptible areas of the body with chlorinated

hydrocarbons appears to keep these parasites in check. Local application of 0.2% coumaphos solution quickly kills flies but only gives protection for 3 days. *H. maculata* was controlled for 1 year by mass application of 0.005% deltamethrin to cattle and horses.[17]

28.7.5 BITING MIDGES

These tiny flies (1–3 mm long) are members of the family Ceratopogonidae, the important genus being *Culicoides*. These flies are blood feeders and as such induce stress in hosts and, can transmit infectious diseases such as bluetongue in sheep, horse sickness, ephemeral fever in cattle. They are also intermediate hosts for nematodes of the genus *Onchocerca*. Because of their importance as vectors of arboviruses,[18] studies have been done on their feeding habits. Cattle and sheep are the most common hosts attacked but some species also feed on birds or dogs. Hypersensitivity to the bites of *Culicoides brevitarsis* results in an allergic dermatitis (Queensland itch or sweet itch) in horses in Australia and North America and is discussed elsewhere. Cattle also show considerable irritation during attacks by large numbers of midges. They react with vigorous stamping of the feet, switching of the tail and continuous movement.

1604 1605

The flies are plentiful in the warmer months and are most active at dawn and dusk. Because of their small size they are capable of being carried long distances by wind. Control of the flies is virtually impossible and most measures to reduce their importance are based on preventing access of the flies to the animals. Repellents, especially dimethyl phthalate or *o*-diethyl toluamide (DEET), are effective on a short-term basis. Antihistamines can be used regularly but are too expensive for general use. Keeping horses away from areas where the flies are present in large numbers is advisable. Backline pour-on treatment of horses with 40 mL of a 4% high CIS permethrin three times weekly gave a good response in 86% of horses.[19] Ivermectin at the recommended dose of 0.2 mg/kg would not produce the serum concentration that would have noticeable effects on blood-feeding *C. variipennis*.[20]

28.7.6 BLACK FLIES; BUFFALO GNATS; SANDFLIES

These small gray to black flies (5 mm) are members of the family Simuliidae and include a number of species and genera. The important flies appear to be *Cnephia pecuarum* which is common in the southern states of the United States, *Simulium arcticum* in northern Canada, *Austrosimulium pestilens* and *A. bancrofti* in Australia, and *Simulium ornatum* in Great Britain. These very small flies occur in most parts of the world. With the exception of *S.*

arcticum and two or three other species common in northern regions of North America black flies are primarily a concern in tropical regions.

Female flies are voracious blood feeders. They are active in the summer months when large numbers emerge from streams and rivers where they have spent their larval and pupal stages.

Austrosimulium pestilens has adapted to reach large numbers, mate, and oviposit within a very short time to utilize the flood situations that occur in northern Australia. The flies congregate in swarms and attack all animals, causing much worry and annoyance. They tend to bite animals around the legs, on the belly and around the head, causing wheals and papules. The annoyance may be so intense that animals stampede or mill about and young animals may be injured or even trampled to death and are frequently separated from their dams. Cattle may spend much of their time wallowing in mud or kicking up dust to keep the flies away. Herding of cattle onto bare areas reduces fly attacks as the flies commonly rest in tall grass, but this reduces feeding. The cause of death is unknown although swelling of the throat causing suffocation, anaphylaxis or direct toxicity are suspected. Filarid worms of *Onchocerca* spp. are transmitted by these flies and their role as an intermediate host of nematodes has been discussed.[21]

A similar situation occurs in northern Canada where large numbers of *Simulium arcticum* have caused severe stress and occasional deaths of cattle introduced into the area of the Athabasca River and similar regions in the province of Saskatchewan. When black fly populations are extreme, previously unexposed cattle develop symptoms of shock resulting from blood loss and cumulative effects of the fly salivary secretions.

Because the larval stages of these flies are passed in flowing streams, large-scale control measures must be directed at killing the larvae at this stage. Aerial distribution of DDT has been effective when added to streams and water supplies or control can be effected by adding insecticides into rivers and canals. However, rapid reinfestation occurs with increased rate of water flow after heavy rains. Annual injection of methoxychlor upstream from major larval sites proved effective in reducing black fly populations, but off-target effects were undesirable.[22] For less ambitious control programs, efforts should be directed towards keeping flies away from animals by the application of repellents or the use of smudge fires. Repellents are of limited use but alcoholic or aqueous solutions and dusts of permethrin, cypermethrin and resmethrin applied to the whole body repelled black flies for some days.[23]

28.7.7 MOSQUITOES

A number of mosquitoes including *Psorophora, Aedes, Mansonia, Culex*, and *Anopheles* spp. are important parasites of domestic animals. When the blood feeding females are present in large numbers they cause stress to animals and have been known to kill young pigs and puppies by the severe anemia they produce. Although such occurrences are rarely recorded the blood loss that can occur in severe infestations is surprising. The stress associated with mosquito attack is sufficient to cause reductions in efficiency, even in mature large animals.

Their most important role is as vectors of disease. *Culex tarsalis, Aedes dorsalis*, and *A. nigromaculis* transmit equine encephalomyelitis. *Culex tritaeniorhyncus* is the principal vector of Japanese B encephalitis in Japan. Various *Culex* species vector Western Equine Encephalitis, Eastern Equine Encephalitis, and West Nile Virus. These viruses can have serious effects on unprotected horses and are transmissible to humans via mosquito bites. Vaccines are available to protect against all of these arboviruses. *Psorophora confinnis* is instrumental in spreading the eggs of *Dermatobia hominis*, the tropical warble fly; and *Mansonia* spp. transmit Rift Valley fever. The filarid worm *Setaria digitata* is also spread by mosquitoes.

Control over a large area must include drainage of collections of still surface water or destruction of the larvae by the addition of any one of a number of insecticides, particularly DDT or Abate. For small groups of animals protection from the attacks of mosquitoes can only be satisfactorily effected by mosquito-proof screens. Temporary protection by repellents such as dimethyl phthalate is partial only. Permethrin, 100 mL of a 0.5% emulsion, applied with an electrostatic sprayer provided greater than 70% protection for at least 72 hours.

28.7.8 HOUSE FLIES (*MUSCA DOMESTICA*)

The common house fly has a worldwide distribution and achieves veterinary importance because it is capable of transmitting, in a mechanical manner, the causative bacteria of many infectious diseases. It is often cited as a means whereby anthrax, erysipelas, and brucellosis are spread but its importance in this regard is largely unproven. House flies are intermediate hosts for the larvae of *Habronema muscae* and *Draschia megastoma*.

The eggs are laid in decaying organic matter of any kind. Larval development is temperature dependent and a life cycle may be completed in 12–14 days so that in warm, wet summers

the fly population may increase very rapidly, causing annoyance to livestock and farm workers.

House fly population management requires frequent and thorough removal of manure and other rich organic matter. In dry weather the manure can be spread thinly on fields but a more dependable method is to place it in a special fly trap, e.g. Baber's fly traps, from which larvae and adult flies cannot escape. Chemical treatments to control flies require application to resting sites on buildings and other facilities, or the placement of baits containing methomyl, propoxur, naled, or dichlorvos at appropriate locations. Development of insecticide resistance can occur rapidly and there are numerous examples of resistance to multiple classes of insecticide at a single location. Rotational use of insecticide classes is absolutely essential in the management of resistance.

1605

1606

Management of house fly populations can be augmented through release of parasitic wasps (Family Pteromalidae) that kill pupae. These tiny wasps (1–2 mm long) actively search for the fly pupae and lay one or more eggs inside. The developing wasps devour the fly within the pupa. They have been found useful adjuncts to other fly control measures when used in confined facilities such as hog barns.[24] Inundative releases at feedlots, where thousands of wasps are released at regular intervals throughout the fly season, has shown some efficacy[25] but requires an integrated approach with good manure management and selective application of insecticides.

To reduce the fly population in buildings is an important procedure in public health work and many measures are recommended. It is not possible to give details of them here because so many factors have to be taken into consideration, including toxicity of the products used for man and animals, development of resistance to the insecticides, and contamination of food products such as milk by the insecticides.

28.7.9

BUSH FLIES (*MUSCA VETUSTISSIMA*)

These flies occur commonly in Australia, in drier areas, and are a cause of stress to livestock in the summer months. Bush flies die out in southern Australia each winter but breeding continues in the north and the regular northern winds that commence about September each year blow flies southwards and repopulate the areas that are now suitable for breeding. *Musca vetustissima* occur in very large numbers and during the day congregate around the eyes, on the lips, on any visible mucous membrane and on wounds to obtain moisture. They are thought to carry contagious ophthalmia of sheep, infectious keratoconjunctivitis of cattle and contagious ecthyma of sheep, to delay the healing of wounds, to contribute to the lesions

produced by buffalo flies (*Haematobia irritans exigua*) and to act as intermediate hosts for the larvae of *Draschia megastoma, Habronema muscae*, and *Thelazia* spp. Control of the fly population is virtually impossible in the areas where it occurs but individual animals may be protected by repellents such as dimethyl phthalate or *o*-diethyl toluamide (DEET). Sprays containing 1% of dichlorvos or crotoxyphos are effective but must be applied daily. Fenvalerate and cypermethrin give excellent relief and lasting protection against the related *Musca autumnalis*. Dung beetles, introduced from Africa, breakup dung pats which will aid in reducing fly numbers.

28.7.10 FACE FLIES (*MUSCA AUTUMNALIS*)

This small fly, indigenous to Europe and Asia, first appeared in North America in 1952 and is now present over large areas of eastern Canada and northeastern and north-central United States. The flies resemble the house fly but are slightly larger. They congregate on the face of cattle, feeding on nasal and lacrimal secretions and saliva. Very large numbers cause a certain amount of stress, cause petechiation in the eye, and are thought to be instrumental in transmitting infectious keratoconjunctivitis (pinkeye) of cattle. Face flies are vectors for the eyeworms, *Thelazia* spp. which infest the conjunctival sacs and lacrimal ducts of domestic animals.

Flies oviposit on fresh cattle manure where larval development takes place. As with all flies development is temperature dependent. In temperate latitudes the flies will over-winter as adults, resting inside homes and other farm structures.

Fly numbers are greatest in summer and cattle are worried particularly when outdoors. Repellents have been extensively used but are not highly successful. Self-applied or hand-applied dusts containing organophosphate insecticides are more extensively used. A dose of 10 mL per animal of 1% cyfluthrin applied as a pour-on reduced fly numbers by 90% and treatment was effective for about 4 weeks.[14] Fenvalerate and cypermethrin give immediate relief, and a lasting reduction in fly numbers when used on fly breeding sites.[26] Reduction of face fly populations on cattle can be achieved through use of synthetic pyrethroids impregnated eartags, but their use is complicated by the presence of insecticide resistant horn flies. Diflubenzuron boluses give 80% control of the immature stages of *M. autumnalis* in the manure for up to 20 weeks.[15]

28.7.11 ## HEAD FLIES (*HYDROTOEA IRRITANS*)

This small fly, similar in appearance to the house fly but having an olive abdomen and yellow wing bases, is found in the United Kingdom and Europe. It is a non-biting muscid fly that swarms around animals and man from late June to September. Breeding is in soil and litter and there is only one life cycle per year. The lesions on sheep are self-inflicted trauma in attempts to alleviate fly irritation. Sores are often large, open, and may be made more severe by bacterial invasion. The wounds may predispose to blowfly strike by *Lucilia sericata*. The pathogens of summer mastitis of cattle can be spread mechanically by muscid flies, and *Areanobacterium pyogenes* has been shown to persist in *H. irritans* for up to 4 days.[27]

Control is difficult and is similar to that used for the other non-biting muscid fly, *M. autumnalis*. Eartags impregnated with 8.5% cypermethrin or 10% permethrin reduce the severity of fly damage in sheep, and tagged ewes give protection to their lambs. However, it is likely that resistance will quickly occur in the same manner as in the face fly. Pour-on applications of synthetic pyrethroids are easier to apply, are cheaper and leave a higher concentration than a spray or an eartag.[28] Cyfluthrin 1% applied as a pour-on at a dose rate of 10 mL per animal reduced fly numbers by 90% and gave 4 weeks protection.[14] Crotoxyphos cream is effective but at least two applications are needed. Head-caps are most effective but are tedious to apply.

28.8 Mite infestations

28.8.1 HARVEST MITES (CHIGGER MITES)

Infestations with trombidiform mites cause dermatitis in all species. Except for *Psorergates ovis, P. bos*, and *Demodex* spp. they are all harvest or grain mites. These mites are primarily predatory on other arthropods associated with harvested grain and infesting animals only secondarily and usually transiently. It is usually the larval stages which are found feeding on animals while the nymphs and adults are free-living. 1606 1607

The larvae of *Pyemotes ventricosus, Neotrombicula autumnalis, Eutrombicula alfreddugesi, E. splendens, E. batatas*, *Trombicula* spp., and some species of *Leptotrombidium* and *Schoengastia* are parasitic on man and most animals, causing dermatitis and, in man, transmitting ricketsial diseases. Nymphs and adults are free-living predators feeding mainly

on arthropods in grain and hay. The larvae are most active in the autumn at harvest time and may cause dermatitis in animals grazing at pasture or those confined in barns and being fed newly harvested grain.

Horses and cattle are usually affected on the face and lips, which, in white-faced horses, may suggest a diagnosis of photosensitization, and about the feet and lower limbs, especially in the flexures. Affected areas are itchy and scaly but, with rubbing, small fragile scabs and absence of hair may become apparent. Infestation of horses with *Trombicula sarcina* causes a severe pruritus and yearlings show irritation by lip-biting their legs and rubbing against stable walls. Stamping is uncommon, and usually occurs when yearlings are stabled on fresh, contaminated bedding.[1] Sheep, when first affected, stamp their feet repeatedly and bite their legs. The skin at the heels, coronet, and pasterns, and sometimes the shank, becomes erythematous and weeps fluid. The mites detach after 3–5 days and leave a small ulcerated area. In light infestations the mites may be confined to the area between the accessory digits, but in heavy infestations the skin over the whole of the lower limbs may be swollen and thickened. The infestation is self-limiting and treatment is not usually necessary but the legs can be washed in 0.25% maldison. Area control of the mite may be obtained by the use of chlorpyrifos either as 0.5% granules, 1.1 kg/ha, or the 22.4% spray at 1.6 kg/ha.[2]

Infestation with *Tyroglyphus* spp. in pigs appears to be manifested by itchiness and the development of fragile scabs about 3 cm in diameter scattered over the body. Unlike the thick scabs of sarcoptic mange, the skin beneath appears normal. The infestations occur in pigs eating dry ground grain from automatic feeders, lesions appearing several weeks after the dry feeding is begun and disappearing spontaneously about 3 weeks later. No treatment is necessary although spraying with malathion is usually recommended. Affected pigs show no ill-effects but the lesions may be mistaken for those of swinepox or sarcoptic mange. The ingestion of large numbers of mites appears to have no ill-effects.

28.8.2

ITCHMITEs (*PSORERGATES OVIS, P. BOS*)

The 'itchmite' has been recorded as a parasite of sheep in Australia, New Zealand, South Africa, the United States, Argentina, and Chile. *Psorergates bos* has also been recorded from cattle in the UK.[1]

28.8.2.1

LIFE CYCLE AND EPIDEMIOLOGY

The entire lifecyle of this mite, eggs, larvae, two nymphal stages, and adults, takes place entirely on the host. In sheep the cycle takes 4–5 weeks. All stages occur in the superficial layers of the skin. The adults are extremely small and can be seen only with the aid of a microscope. Only the adults are mobile on the skin surface and they effect spread of the disease by direct contact. In sheep this often occurs between recently shorn animals when contact is close and prolonged such as when shorn sheep are packed in yards after shearing, or from ewe to lamb while suckling. Mite feeding activity, in addition to excreta causes skin irritation leading to rubbing and biting of the affected parts (principally the sides, flanks, and thighs) and raggedness, sometimes shedding, of the fleece. Wool over these areas becomes thready and tufted and contains dry scales.[2]

28.8.2.2

PATHOGENESIS

The skin shows no gross abnormality other than an increase in scurf. Histologically there is hyperkeratosis, desquamation, and increased numbers of mast cells.[3] The irritation appears to be a hypersensitivity and results in biting and chewing of the fleece on the flanks and rump behind a line approximately from the elbow to the hips. In the individual sheep and in flocks the disease spreads slowly so that it may be several years before clinical cases are observed and an appreciable number are visibly affected. The incidence of clinical cases in a neglected flock may be as high as 15%. Sheep on poor nutrition have significantly higher mite populations, more scurf and greater fleece derangement.[3] Affected sheep may become tolerant after 1–2 years and show no signs, even though they remain infested.

Amongst sheep, Merinos are most commonly affected. The highest incidence is observed in this breed, particularly in areas where the winter is cold and wet. There is a marked seasonal fluctuation in the numbers of mites; the numbers are very low in summer, commence to rise in the autumn, and peak numbers are found in the spring. Spring or summer shearing exacerbates the decline in numbers. Clinically, the disease resembles

louse infestation, but may be distinguished on the smaller proportion of the flock affected (10–15%), the less severe irritation and tendency of the sheep to bite those areas it can reach. Hence lesions are confined to parts of the flank and the hindquarters and the wool tufts have a chewed appearance.

28.8.2.3

CLINICAL FINDINGS

Diagnosis depends on finding the mites in a skin scraping. The selection of sheep with excess scurf and fleece derangement increases the chance of finding mites and in the absence of lice, ked, and grass seed infestation, about 75% of such sheep prove positive for *P. ovis*. The wool should be clipped as close as possible, the skin smeared lightly with oil and scraped over an area of about 25 cm^2. The mites have a seasonal incidence and may be very difficult to find in summer and autumn. For best results the scraping should be made on the ribs or shoulder in winter or spring. Scrapings are usually teased out in oil and examined microscopically without digestion. A number of scrapings may be needed from each sheep before mites can be demonstrated. Because of the difficulty of finding mites in summer and autumn, sheep dipped at that time cannot be said to be free of infestation until they prove negative on skin scraping in the following spring, when mite numbers should be at the highest levels.

28.8.2.4

TREATMENT AND CONTROL

There is no compound available that will eradicate itchmite after a single treatment. Arsenic, lime sulfur, or finely divided sulfur have been used and markedly reduce the number of mites. Because the mites are slow to build up, dipping every second year will mask the signs of infestation. However, arsenic is no longer used in most countries. Finely divided rotenone by itself or mixed with the synergist piperonyl butoxide reduces the mite population. It is usually combined with an organophosphate to include lice and ked control in the one product. Phoxim, an organophosphorus compound, has good activity but two dippings 1 month apart are necessary to eradicate infestations. Amitraz causes a marked reduction in mites that will be maintained for some months.

A single subcutaneous injection of 0.2 mg/kg ivermectin freed sheep of mites up to 56 days post-treatment.[4] However these sheep would have to be examined over a longer period to insure eradication. Other macrocyclic lactone products, in various formulations, have been shown to have good efficacy.

1607

1608

28.8.3

DEMODECTIC MANGE (FOLLICULAR MANGE)

Mites of *Demodex* spp. infest hair follicles of all species of domestic animals. The disease causes little concern but in cattle and goats there may be significant damage to the hide and, rarely, death that may result from gross secondary bacterial invasion.

28.8.3.1

ETIOLOGY

Mites infesting the different host species are considered to be specific and are designated as *Demodex bovis* for cattle, *D. ovis* for sheep, *D. caprae* for goats, *D. equi* for horses, and *D. phylloides* for pigs.

Demodicosis may occur in farm animals of any age, especially those in poor condition but most cases in cattle occur in adult dairy cattle in late winter and early spring. This differs from the well-known condition in the dog which occurs in young, immunodeficient animals.

28.8.3.2

LIFE CYCLE AND EPIDEMIOLOGY

The entire life cycle is spent on the host. Adult mites invade the hair follicles and sebaceous glands which become distended with mites and inflammatory material. The life cycle consists of the egg, larval, and two nymphal stages. The disease spreads slowly and transfer of mites is thought to take place by contact, probably early in life. Calves can acquire mites from an infected dam in half a day.[1] However in horses grooming instruments and rugs may transmit infection.

28.8.3.3

PATHOGENESIS

Invasion of hair follicles and sebaceous glands leads to chronic inflammation, loss of the hair fiber and in many instances the development of secondary staphylococcal pustules or

small abscesses. It is these foci of infection which cause the small pinholes in the hide which interfere with its industrial processing as well as reducing the value dramatically. In most farm animals the lesions are difficult to see externally and only the advanced ones will be diagnosed.

28.8.3.4

CLINICAL FINDINGS

The important sign is the appearance of small (3 mm diameter) nodules and pustules which may develop into larger abscesses, especially in pigs and goats. The small lesions can be seen quite readily in short-coated animals and on palpation feel like particles of bird-shot in the hide. In severe cases there may be a general hair loss and thickening of the skin in the area, but usually there is no pruritus and hair loss is insufficient to attract attention. The contents of the pustules are usually white in color and cheesy in consistency. In large abscesses the pus is more fluid. In cattle and goats the lesions occur most commonly on the brisket, lower neck, forearm, and shoulder, but also occur on the dorsal half of the body, particularly behind the withers. Larger lesions are easily visible but very small lesions may only be detected by rolling a fold of skin through the fingers. In horses the face and around the eyes are predilection areas. Demodicosis in pigs usually commences on the face and spreads down the ventral surface of the neck and chest to the belly. There is little irritation and the disease is observed mainly when the skin is scraped at slaughter. The disease may be especially severe in goats, spreading extensively before it is suspected and in some instances causing deaths. Severe cases in goats commonly involve several skin diseases such as mycotic dermatitis, ringworm, besnoitiosis and myiasis. Demodicosis is rare in sheep. In this species pustules and scabs appear on the coronets, nose, tips of the ears, and around the eyes, but clinical signs are not usually seen and mites may be found in scrapings from areas of the body not showing lesions.

28.8.3.5

CLINICAL PATHOLOGY

The characteristically elongated mites are usually easy to find in large numbers in the waxy material which can be expressed from the pustular lesions. They are much more difficult to isolate from squamous lesions. Lesions in hides can be detected as dark spots when a fresh hide is viewed against a strong light source. However, lesions may not be readily seen until the hair has been removed and the skin has been soaking for some time.

28.8.3.5.1

DIFFERENTIAL DIAGNOSIS

- The commonest error is to diagnose the disease as a non-specific staphylococcal infection
- In cattle and goats the disease often passes unnoticed unless the nodules are palpated
- Deep-seated ringworm in horses has much in common with demodicosis
- A satisfactory diagnosis can only be made by demonstration of the mite.

28.8.3.6

TREATMENT AND CONTROL

Repeated dipping or spraying with the acaricides recommended for other manges is usually carried out but is more to prevent spread than cure existing lesions. Ivermectin which does not eradicate the infection in dogs, possibly because of the difficulty in getting the acaricide to the mite, has been reported to cure 98% of beef bulls when used at 0.3 mg/kg.[2] Ivermectin in a premix, fed for 7 consecutive days has been reported to clear the infestation in pigs.[3]

28.8.4

SARCOPTIC MANGE (BARN ITCH)

Sarcoptic mange occurs in a wide variety of host species causing a severe puritic dermatitis. While in most countries it has been a major problem and was a reportable disease the advent of macrocyclic lactone endectocides has reduced the incidence of disease dramatically.

28.8.4.1

ETIOLOGY

The causative mite, *Sarcoptes scabiei*, is usually considered to have a number of varieties each generally specific to a particular host species. Morphological, immunological and

molecular research confirms the close relationship among the varieties,[1] but do not explain the biological differences, particularly with respect to host specificity. Because host specificity is not strict and transference from one host species to another can occur there is some concern when attempting to control the disease.

Animals in poor condition appear to be most susceptible, but conditions, especially overcrowding, in which sarcoptic mange occurs often go hand in hand with poor feeding and general poor husbandry. The disease is most active in cold, wet weather and spreads slowly during the summer months.

28.8.4.2

LIFE CYCLE AND EPIDEMIOLOGY

Female mites form shallow burrows in the lower stratum corneum of the skin in which they deposit eggs. Development for both sexes includes a larval stage, two nymphal stages prior to molting to the adult. All life cycle stages, except the eggs, can be found moving on the skin surface and are thus easily transferred to other hosts. The normal exfoliation of the skin eventually exposes the tunnels exposing eggs as well. The life cycle from egg to egg takes 10–13 days.

Although direct contact between hosts is the most effective method of transmission inert materials such as bedding, blankets, grooming tools, and clothing may act as carriers. Adult mites do not usually survive for more than a few days away from the host but in optimum laboratory conditions they may remain alive for up to 3 weeks. In pigs adult sows are often the source of infestation for young pigs even though they show no signs of the disease. Large numbers of mites can often be found in the ears of normal sows and the mites are transmitted soon after farrowing. Significant scratching does not occur until a hypersensitivity develops some 8–10 weeks later and may continue until slaughter.[2] A small proportion of young pigs do not develop a hypersensitivity and these become chronically affected.[2]

1608 1609

Amongst domestic species pigs are most commonly affected, but it is an important disease in cattle and camels and occurs in sheep. It has been a notifiable disease in most countries, because of its severity, but a decline in prevalence accompanying the advent of new therapeutics has resulted in the removal of this requirement in some countries. People handling infested animals may become infected but lesions will disappear if further contact is prevented.

Infested animals develop protective immunity[3] and are able to clear challenge infestations rapidly. A proportion of infested hosts do however remain chronically infested and mite populations may show a post-partum recrudescence thereby facilitating transfer to the susceptible offspring.

28.8.4.3

PATHOGENESIS

Young animals, in particular piglets, become infected in the first few weeks of life and develop a hypersensitivity within 8–10 weeks. This allergic phase lasts for 8–9 months[4] and during this time affected animals are constantly itchy. The disease, if untreated, progress to a localized crust formation characteristic of a chronic hyperkeratotic state.

Many infestations in pigs have little or no effect on weight gain although there is some controversy[5] and treatments improve productivity (see below). There are suggestions in other hosts of reduced feed efficiency. In some pigs the loss of condition, production and vitality may be severe, and the appearance of affected animals is esthetically displeasing. Erythema, papules and intense pruritis may be seen. Few mites may be necessary to cause a reaction in a previously sensitized animal. A chronic condition is uncommon but is seen in pigs with an immunodeficiency.

In cattle and camels, severe hypersensitivity lesions occur and often lead to death. Sheep initially show an intense pruritus and rub the affected part against fences or bite at the skin. Later papules and vesicles occur and the skin becomes thickened, covered with pale scabs and the hair is lost.[6]

28.8.4.4

CLINICAL FINDINGS

Early lesions are characterized by the presence of small red papules and general erythema of the skin. The affected area is intensely itchy and frequently excoriated by scratching and biting. Loss of hair, thick brown scabs overlying a raw surface, and thickening and wrinkling of surrounding skin soon follow. In pigs the lesions commence on the trunk, in sheep and goats on the face, in cattle on the inner surface of the thighs, the underside of the neck and brisket and around the root of the tail, and in horses and camels on the head and neck. Except in sheep where the lesions do not spread to the woolled skin, lesions become widespread if neglected and such animals may show systemic effects including emaciation, anorexia, and weakness, and in neglected cases death may occur.

The course of sarcoptic mange is rather more acute than in the other forms of mange and may involve the entire body surface of cattle in a period as short as 6 weeks.

28.8.4.5

CLINICAL PATHOLOGY

Necropsy examinations are not usually undertaken. Deep scrappings which draw blood are required for accurate diagnosis and must be taken from the edges of any evident lesions (scrappings taken from the central portions of lesions are very often negative). Examination of scrapings either directly or after digestion in 10% potassium hydroxide will reveal mites and/or eggs. When practical multiple scrapings from affected animals should be taken. Examination of the ear wax of pigs often shows mites when none can be seen in scrapings.

Change in behavior, a result of the intense pruritis, have been used in swine as an initial diagnostic tool. An increase in the rubbing index is indicative of infestation, but other clinical confirmation is required.[7]

An ELISA for detection of antibodies to *Sarcoptes scabiei* has been developed.[8] The test has high specificity and moderate sensitivity, being more sensitive in young animals undergoing their first infestation. It has been shown to work well in herd level eradication programs and functions afterward as an effective surveillance tool.[9]

28.8.4.5.1

DIFFERENTIAL DIAGNOSIS

- Sarcoptic mange is the only mange which occurs in pigs. It can be confused with infestation with *Tyroglyphus* spp. mites or lice, or with swinepox, parakeratosis, infectious dermatitis, pityriasis rosea, and ringworm. In most of these diseases there are clinical features which are characteristic and final diagnosis can be made on the presence or absence of the mite
- The same comments apply to the differentiation in cattle of sarcoptic mange from chorioptic and psoroptic mange and from chlorinated naphthalene poisoning and ringworm
- Horses may be affected by psoroptic or chorioptic mange but the lesions are most common at the base of the mane and tail and at the back of the pastern respectively

- Infestation with the trombidiform mites and photosensitization may resemble sarcoptic mange
- The disease is uncommon in sheep.

28.8.4.6

TREATMENT AND CONTROL

Macrocyclic lactone endectocides (including ivermectin, eprinomectin, moxidectin, and doramectin) are the preferred products for treatment of sarcoptic mange. Use of these products in pour-on or injectable formulations are highly efficacious when used at the label recommended dose. Because of the residual activity of these compounds[10] retreatment is not usually necessary although moxidectin given subcutaneously at 0.2 mg/kg to infested sheep resulted in a rapid clinical improvement but did not eliminate the mites. Two doses 10 days apart resulted in negative skin scrapings by 14 days post-treatment.[11] A single injection to cattle eliminated the mites by day 14.[12] The resolution of the lesions may take considerable time, but should not be misconstrued as product failure.

Prefarrowing treatment with ivermectin to prevent transmission to the newborn piglets improves weight gains and early feed conversion.

If other treatments are used they must be thoroughly applied so that all parts of the skin, especially under the tail, in the ears and between the legs are wetted by the acaricide. Although buildings, bedding, and other inert materials do not support the mite for more than a few days they should also be treated unless they can be left in a dry state for 3 weeks.

Treatments should be repeated three times at 7-day intervals. For sows this should commence 3 weeks before farrowing. Special attention should be paid to the ears. Trichlorfon, maldison (0.5%), diazinon (0.02%), coumaphos (0.05–0.1%), fenchlorphos, chlorfenvinphos, amitraz (0.1%), and phoxim (0.025%) have been used. All animals should be treated. Phosmet 20% applied as a pour-on at weaning eliminated *Sarcoptes* and allowed 12% increase in live weight gain.[13]

28.8.5

PSOROPTIC MANGE (SHEEP SCAB, BODY MANGE, EAR MANGE)

Psoroptic mange is of greatest importance in sheep, in which it causes sheep scab, but it is also responsible for body mange in cattle and horses and ear mange in horses, sheep, goats, and rabbits. The disease is a major animal welfare concern.[1]

28.8.5.1

ETIOLOGY

The various species of *Psoroptes* have now been reduced to two or three species.[2] Based on molecular evidence[3] *P. ovis*, *P cuniculi*, and *P. cervinus* are identical despite differences in morphology and biology. It is clear that *P. ovis* from cattle and sheep are identical[4] although cross-transmission is not always successful.[5] *P. equi* occurs on horses, donkeys, and mules in Great Britain and *P. natalensis* on cattle and the water buffalo. The ear mites are all *P. cuniculi* and recent work has suggested this is a variant of *P. ovis* adapted to the aural environment. *P. cervinus* assumes a dual role, being an ear mite of the American bighorn and a body mite of the wapiti.

28.8.5.2

LIFE CYCLE AND EPIDEMIOLOGY

Psoroptic mange is a major disease in sheep which was once virtually eliminated in most progressive countries where wool production is an important industry. With the cessation of organophosphate dips in the UK there has been a resurgence of the problem. The

disease in cattle was widespread in the United States but has now largely been brought under control. It can spread rapidly and cause serious losses in cattle if neglected as shown by the serious losses that can occur in feedlots. The ear manges cause irritation and, in horses, a touchiness around the head.

Psoroptic mites abrade the surface and feed on lipid exudate, bacteria, and skin debris.[6] Erythrocytes are not normally a constituent of the diet and may be accidentally ingested when host scratching results in skin breakage.[6] They cause the formation of scabs, under which they live. The eggs are laid on the skin at the edge of a scab and hatch in 1–3 days, although this is prolonged if eggs are not in contact with the skin. There are the usual larval and nymphal stages and the whole life cycle is complete in 10–11 days.[7] All stages are capable of survival away from the host for up to 10 days and under optimum conditions adult females may survive for 3 weeks.

Optimum conditions for development include high humidity and cool temperatures. Thus the disease is most active in autumn and winter months. This is a result of not only increased activity of the mites but also the more rapid development in housed animals and the tendency for the disease to be most severe in animals in poor condition. When conditions are adverse, as in summer, mites survive in sheep in protected parts in the perineum, in the inguinal and interdigital regions, the infraorbital fossae, inside the ear and the scrotum. Spread occurs from sheep to sheep but transmission from infected premises and by passive spread of pieces of wool also occurs.

While *P. ovis* has been shown to survive for up to 17 days away from the host,[8] no natural transmission has taken place where premises have been rested for more than 10 days.[5] Premises left free of sheep for at least 2 weeks can be assumed to be safe.[5] If cattle are housed in stanchions that prevent grooming infestation will be more severe.[7] Although individual mites survive for only 4–6 weeks the disease is continuous and a very rapid increase in mite numbers may occur.[7]

The life cycle of the other species is thought to be similar. Spread of ear mite in horses can occur by grooming or by the use of infected harness.

28.8.5.3

PATHOGENESIS

The mite migrates to all parts of the skin and prefers areas covered with hair or wool. Salivary secretions and mite excreta contain proteinases that result in a severe allergic

pruritis. The exudation of serum accumulates to form a crust. In cattle the mites are most active at the edge of the crust and the lesion spreads peripherally. Infested calves have lower weight gains, lower feed conversion and lower energy retention than non-infested calves.[7] In sheep the mites are more generally distributed and bacterial invasions of the skin are more common.[4]

28.8.5.4

CLINICAL FINDINGS

28.8.5.4.1

Sheep

Cutaneous lesions may occur on any part of the body but characteristically in badly affected sheep they are most obvious on the sides. Very early lesions are small (6 mm diameter) papules which ooze serum. Attention may be attracted to the area by raggedness of the wool caused by biting and scratching. In older lesions thin yellow crusts are present and the wool commences to shed. The wool may contain large masses of scab material which bind the fibers together in a mat. Under suitable conditions the infestation spreads rapidly and in 6–8 weeks three-quarters of the body may be affected.

In a typical outbreak of sheep scab many animals are affected and show itchiness and shedding of the fleece. Some become markedly emaciated and weak, and deaths may occur. However, it is possible to have the disease in a flock at a very low level of incidence and with minimal lesions. This usually occurs when the sheep are highly resistant because of good nutrition, or climatic conditions are adverse for mite development, or treatment has been carried out but has been incomplete. In such cases there may be little or no clinical evidence of the disease and a careful search for latent cases may be necessary. This is facilitated by packing the animals into a confined space, so that the mites become active, and watching for signs of itchiness.

Behavioral changes in infested sheep are dramatic with sheep biting at the affected areas, rubbing or scratching. In addition infested sheep exhibited stereotypic behaviors typical of animals under stress.[1] These changes combine to reduce productivity. Animals exhibiting these changes should be carefully examined by palpating the surface of the skin in search of papules and scabs. Special attention should be paid to the ears, the base of the horns, the infraorbital fossa and the perineal and scrotal areas in rams.

28.8.5.4.2

Goats

Lesions can vary from a dry crusty scab on the external ear canal with no clinical signs to severe lesions covering much of the body and causing death. However, it is commonly an ear mite, feeding on whole blood, and causing the production of scabs which vary from a single layer lining the large sulcus at the base of the concha to abundant laminated scab formation occluding the meatus. In severe cases the poll may be affected, and scabs may also be found on the pasterns. Female goats serve as the source of infection for the kid; mites may be found by 5 days and clinical signs are seen by the 3rd week of life.[9] *Raillietia* may also be found in the ear of goats but *Raillietia caprae* is easily differentiated microscopically as all legs are on the anterior part of the body.

28.8.5.4.3

Horses

P. equi causes the production of large, thick crusts on those parts of the body carrying long hair, the base of the mane and the root of the tail, and hairless areas such as the udder, prepuce, and axilla. Affected parts are itchy, the hair is lost and with constant rubbing the surrounding skin becomes thickened. *P. cuniculi* infestations in horses cause severe irritation in the ear accompanied by discharge, shaking of the head, rubbing of the head, and tenderness of the poll.

28.8.5.4.4

Cattle

Typical lesions appear first on the withers, neck, and around the root of the tail. In severe cases they may spread to the rest of the body. The lesions are intensely itchy. They commence as papules but soon are covered with a scab which enlarges peripherally and coalesces with other lesions so that very large areas of skin may become involved. The hair is lost, the skin becomes thickened, wrinkled, and covered with scabs. Badly affected animals becomes weak and emaciated, and may die.

1610

1611

28.8.5.5

CLINICAL PATHOLOGY

The mites can be easily demonstrated in scrapings taken from the edges of the lesions. Examination is facilitated by prior digestion of the scraping in warm, 10% potassium hydroxide solution.

An ELISA has been developed for diagnosis of *Psoroptes* infestation in sheep.[10] It has been applied to monitoring of infestations as part of efficient control programs.[11]

28.8.5.5.1

DIFFERENTIAL DIAGNOSIS

- Severe cases of psoroptic mange in sheep are similar to mycotic dermatitis except that there is no itching in the latter. Disease causing itchiness such as scrapie, ked, and louse infestations and infestations with *Psorergates ovis* and harvest mites do not have typical cutaneous lesions and the latter group can usually be detected by examination for the causative parasites
- In horses attention is drawn to the condition because of the horse rubbing its head, by swelling around the base of the ear, or by resentment to the bridle passing over the ears. In some horses the affected ear may droop.

28.8.5.6

TREATMENT AND CONTROL

Macrocyclic lactone endectocides are used most frequently for control of psoroptic scabies. Cattle treated with ivermectin must be separated from non-infested cattle for between 9 and 14 days, otherwise spread and re-infection[12] may occur. In sheep two treatments of ivermectin 0.2 mg/kg subcutaneously are necessary to eliminate infestations.[13]

Moxidectin applied as a 0.5% pour-on at 0.5 mg/kg to cattle is effective against *P. ovis* as well as lice and *Chorioptes bovis*[14] and was equally effective against *P. ovis* as 0.2 mg/kg by subcutaneous injection.[15] In sheep, although a single subcutaneous dose of 0.2 mg/kg moxidectin gave a rapid clinical improvement, two doses 7 days apart were necessary to eliminate mites.[16] In large scale field use, sheep receiving a single injection in the autumn remained free of the infestation throughout the winter, while two injections 10 days apart were effective in treating outbreaks.[17]

Doramectin injectable at 200 μg/kg was highly effective in eliminating mites in scrapings of infested cattle.[18] The same treatment was found to protect cattle from infestation for up to 3 weeks.[18]

If sheep are to be dipped, it is important to wet the skin thoroughly and pay special attention to severe cases where mites are likely to be present in inaccessible sites on the

body. Thus a plunge dip is almost essential and the sheep must be kept immersed in the dipping fluid for at least one minute. Prior shearing may be advisable but may lead to further spread of the infestation. Care must be taken to insure that the concentration of the acaricide in the dip is maintained, especially when large numbers of sheep are being treated. Badly affected animals should be set aside and inaccessible sites including ears, horn bases, and perineum treated manually with the dipping fluid. Dipped sheep should not be returned to their pastures, nor to the barn unless the latter has been thoroughly cleaned and sprayed with the dipping fluid.

Diazinon (0.01%), propetamphos (0.0125%), and flumethrin (0.055%) will all eliminate *P. ovis* from sheep with a single dipping and will give at least 4 weeks of protection.[19] Coumaphos (0.1%), phoxim (0.05%), and amitraz (0.05%) require two treatments at 7–10 day intervals to eliminate infestations. The synthetic pyrethroids are variable in their efficacy. Flumethrin, used as a non-stripping dipping compound, eradicated *P. ovis* from sheep when used at 55 ppm and gave at least 7 weeks of protection.[20] Fenvalerate (0.05%) used twice will also clear infested cattle, but another synthetic pyrethroid, cypermethrin, when used at 150 ppm did not eliminate infestations after three treatments.[21]

In horses, affected ears should be cleaned of all wax and ear preparations containing benzene hexachloride should be used at weekly intervals. Local treatment of diazinon or propetamphos could also be used. Benzyl benzoate is a safe and effective treatment when given every 5 days for three treatments. Ivermectin is highly effective against *P. equi*.[22]

Eradication of sheep scab on an area basis is usually undertaken by quarantine and compulsory treatment of all susceptible animals in the area at the same time. Now that there are effective treatments that do not require dipping, eradication of scab from areas should be more easily accomplished. The necessity to dip all animals in the area during a short period presents difficulties and the cost of construction of dips and lack of desire to dip in cold climates are other obstructing factors. The use of pour-ons or injections is an attractive alternative to autumn dipping, and has the added advantage of providing helminth control in late season lambs and in ewes. Further, even pregnant animals can be yarded and treated by subcutaneous injection or pour-on as long as care is taken in the yards. Where it is desired to keep the disease at a low level short of eradication, the disease is made notifiable, movement of stock is restricted and infested farms are quarantined.

28.8.6

CHORIOPTIC MANGE (TAIL MANGE, LEG MANGE, SCROTAL MANGE)

Chorioptic mange is the commonest form of mange in cattle and horses. While the primary effect on cattle is esthetic damage there are production effects in dairy animals.[1,2] In horses leg mange is a source of annoyance and inefficiency at work. In sheep it affects the scrotum and may cause a decrease in fertility.[1]

28.8.6.1

ETIOLOGY

Chorioptic mites were formerly named according to the host species but those on cattle, horses, goats, and sheep are now considered to be one species, *Chorioptes bovis*. Another species, *C. texanus*, has been reported on goats, cattle, and Canadian reindeer. In cattle, the mites are much more active in the latter part of the winter and tend to disappear in cattle at pasture. This diminution in activity is not noted in cattle kept housed in the summer.

28.8.6.2

LIFE CYCLE AND EPIDEMIOLOGY

Chorioptes bovis feed on the skin surface, abrading the upper layers with their mouthparts and contaminating the area with salivary secretions and excreta. Developmental stages are similar to that of *Psoroptes* and a complete cycle, from egg to adult, requires approximately 3 weeks. The number of parasites is influenced by temperature and humidity; the mite populations beginning to increase on sheep in early autumn, numbers reach a peak in late autumn or early winter and decline in spring. In cattle the cycle is longer, peak numbers occurring in late winter and early spring and declining in summer. 1611

Transmission is probably effected by direct contact in most instances although in animals housed in barns, grooming tools may be an additional method of spreading the disease. Infestation of bedding is not a common method of transmission. 1612

In horses, the parasites occur almost entirely in the long hair on the lower parts of the legs and are rarely found on other parts of the body. In cattle the disease is most evident in the winter, lesions occurring most commonly on the perineum, and back of the udder, extending in severe cases to the backs of the legs and over the rump. In the summer months the mites persist in the area above the hooves, particularly the pasterns of the hind leg. In sheep, lesions are confined to the wool-less areas, chiefly the lower parts of the hindlegs and scrotum. Rams are more heavily infected than ewes and probably infect ewes while copulating. Lactating ewes probably act as the source of infection for lambs.

28.8.6.3

PATHOGENESIS

The mites cause an allergic, exudative dermatitis; the yellowish serous exudate coagulates and breaks as the hair grows so that small scabby lesions are seen on the hair. In horses the mites cause severe irritation and itchiness. The initial lesion in cattle is a small nodule which exudes serum causing matting of the hair. In severe cases these coalesce to form heavy scabs and cause thickening and wrinkling of the skin. Mites can be isolated from

many animals which show no clinical evidence of the disease. While most cases do not cause any symptoms, a rapidly spreading syndrome characterized by coronitis, intense irritation and a marked fall in milk production has been reported. *C. bovis* is a common parasite of sheep in the United States, New Zealand, and Australia, and causes an allergic exudative dermatitis on the scrotum of rams. This may cause a rise in temperature of the scrotal contents and a severe testicular degeneration if the lesion has an area greater than 10 cm^2.[1]

28.8.6.4

CLINICAL FINDINGS

The first sign in horses is usually violent stamping of the feet and rubbing of the back of the hind pasterns on wire, rails, or stumps. This is most evident during periods of rest and at night. Examination of the area is difficult because of the long hair present and the horses may resent manipulation. In cases of long duration the skin is seen to be swollen, scabby, cracked, and usually greasy; small amounts of serous exudate may be attached to most hair in the affected area.

Cattle show little evidence of cutaneous irritation but the small crusty scabs (3 mm diameter) on the escutcheon, udder, and thighs are unsightly. Although the mites appear to cause little trouble in the summer, occasional animals are seen which have thick, crusty scabs on the skin, just above the coronets and around the muzzle.

The main lesion in sheep is seen on the scrotum of rams where an allergic dermatitis results in the production of a yellowish serous exudate over areas from a few millimeters to several centimeters.[1]

28.8.6.5

CLINICAL PATHOLOGY

Scrapings from the affected areas usually contain large numbers of mites.

28.8.6.5.1

DIFFERENTIAL DIAGNOSIS

- Greasy heel in horses resembles chorioptic mange except that pain is more evident in the former and itchiness in the latter. It has been suggested that the two diseases are etiologically related
- The lesions in cattle may go unnoticed but are not likely to be mistaken for those of any other disease with the possible exception of other manges. The presence of chorioptic mites in footrot and mucosal disease lesions may be purely

coincidental, but cases of chorioptic mange which have lesions around the coronet and muzzle may be mistaken for one of the erosive diseases

- Sheep with itchy, scabby legs may be infested with other forms of mange or have contagious ecthyma or strawberry footrot.

28.8.6.6

TREATMENT AND CONTROL

The macrocyclic lactone endectocides have shown efficacy against *Chorioptes* spp., but eradication of the parasites from a herd is difficult. Moxidectin 0.5 mg/kg applied as a pour-on eliminated *C. bovis* as well as sucking lice and *Psoroptes ovis*.[3] When given as a single injection of 0.2 mg/kg there was a marked decline in the number of mites but few cattle were cleared of infection.[4] Doramectin has high efficacy at the label rate in cattle, but a single treatment did not clear mites from all of the trial animals.[5] Treatment with eprinomectin at recommended rates was completely effective, but mites persisted for at least 14 days.[2]

Two doses of 2 mg/kg flumethrin applied to the whole body 1 week apart eliminates mites from cattle, while treatment of 2 mg/kg was successful if applied to the caudal region.[6] Fenvalerate 0.05% also killed all mites while amitraz 0.05% removed 98%.[7] Phoxim 0.05% and 0.1% used twice at 10-day intervals has also eradicated the infection from cattle.[8] Other compounds if used repeatedly will reduce mite numbers but recrudescences may occur. Ivermectin 0.2 mg/kg given subcutaneously on two occasions reduced but did not eliminate the infestation on cattle. A single treatment of infested horses with ivermectin paste did not remove all mites but when combined with hair removal, washing encrusted areas with oil of salicylic acid and the later removal of crusts with a stiff brush, eradication was achieved.[9]

29 Chapter 29 Metabolic diseases

29.1 Introduction

Among domestic farm animals, the metabolic diseases achieve their greatest importance in dairy cows and pregnant ewes. In the other species, these diseases occur only sporadically. The high-producing dairy cow always verges on abnormal homeostasis and the breeding and feeding of dairy cattle for high milk yields is etiologically related to metabolic disease so common in these animals.

The salient features of the common metabolic diseases of farm animals are summarized in Table 29.1.

29.1.1 Periparturient period in cattle and sheep

As milk production in dairy cows increases and as herds become larger, the incidence of metabolic disease increases. In dairy cows, the incidence of metabolic diseases is highest in the period commencing at calving and extending until the peak of lactation is reached and their susceptibility appears to be related to the extremely high turnover of fluids, salts and soluble organic materials during the early part of lactation. With this rapid rate of exchange of water, sodium, calcium, magnesium, chlorides and phosphates, a sudden variation in their excretion or secretion in the milk or by other routes, or a sudden variation in their intake because of changes in ingestion, digestion or absorption, may cause abrupt, damaging changes in the internal environment of the animal. It is the volume of the changes in intake and secretion and the rapidity with which they can occur that affects the metabolic stability of the cow. In addition, if the continued nutritional demands of pregnancy are exacerbated by an inadequate diet in the dry period, the incidence of metabolic disease will increase. The effect of pregnancy is particularly important in ewes, especially those carrying more than one lamb.

29.1.2 Transition period in dairy cows

The literature on managing the transition period of the cow from 3 weeks before parturition to 3 weeks after parturition to optimize health and productivity has been reviewed.[1] It is a crucial stage in the production cycle of the dairy cow; no other period can affect subsequent production, health, and reproductive performance so greatly.[1,2] The success of the transition period effectively determines the profitability of the cow during that lactation. Nutritional or

management limitations during this time may impede the ability of the cow to reach maximal milk production. The primary challenge faced by cows is a sudden and marked increase of nutrient requirements for milk production, at a time when dry matter intake and thus nutrient supply, lags far behind. Dry matter intake typically declines during the final week before parturition. This decline and changes in endocrine profiles contribute to elevated blood nonesterified fatty acids which have been related to the occurrence of lipid-related metabolic diseases such as fatty liver and ketosis. The magnitude of the decline in intake as parturition approaches may be a better indicator of metabolic health of post partum cows than level of intake. Diet, body condition score and parity influence dry matter intake and energy balance. The occurrence of diseases during the transition period results in lost milk production during the time of illness and often for the entire lactation.

A key area of the biology of transition cows is lipid metabolism.[3] Excessive lipid metabolism from adipose tissue is linked with greater incidences of periparturient diseases. Fatty livers have been described in ketotic cows in the 1950s. Hepatic fat accumulation was then noted in normal cows during early lactation. This was followed by a description of a ‘fat mobilization syndrome' in early lactation, in which cows mobilized body lipids from adipose tissue and deposited lipids in the liver, muscle, and other tissues. This was followed by descriptions of elevated non esterified fatty acid concentrations during the last 7 days before calving being associated with a greater incidence of ketosis, displaced abomasum and retained fetal membranes but not of milk fever. Understanding the metabolism of NEFA by the liver is a critical component of understanding the biology of the transition cow. Extreme rates of lipid mobilization lead to increased uptake of NEFA by the liver and increases triglyceride accumulation. If this lipid infiltration becomes severe, the syndrome of hepatic lipidosis or fatty liver may result, which can result in a prolonged recovery from other diseases, increased incidence of other diseases, and increased susceptibility to induction of ketosis.

It is now known that lipid metabolism in the prepartum dairy cow is important in the occurrence of displaced abomasum.[4,5] Significant risk factors for displaced abomasum included a negative energy balance prepartum (as estimated from plasma NEFAs), a high body condition score, suboptimal feed bunk management prepartum, prepartum diets containing >1.65 Mcal of net energy for lactation/kg of dry matter, winter and summer seasons, high genetic merit and low parity.[5]

1613 1614

Table 29.1 Salient features of metabolic diseases of farm animals

Disease	Etiology and epidemiology	Diagnosis	Treatment	Control
Milk fever of cattle	Hypocalcemia. Occurs primarily in dairy cows after 3rd lactation. Also in beef cows. 48 hours before or after calving and in mid-lactation	Low levels of serum calcium	Calcium salts IV, SC	Dietary management of anions-cations
Downer cow	Complication of milk fever; recumbent too long before treatment	Clinical findings. Serum levels of CPK	Supportive therapy	Early treatment of milk fever cases
Acute hypokalemia of cattle	In lactating dairy cows treated with corticosteroids for recurrent ketosis, and mastitis	Low levels serum potassium	Potassium chloride IV	Avoid excessive use of isoflupredone for recurrent ketosis
Lactation tetany of mares	High producing lactating mares being nursed by vigorous well-nourished foal a few weeks of age	Low levels serum calcium	Calcium borogluconate	No reliable method available
Hypomagnesemic tetany (lactation tetany)	Lactating dairy cows on lush fertilized pastures. Also in beef cows before and after calving	Low levels of serum magnesium	Magnesium salts IV	Supplementation of diets at strategic times with magnesium salts
Ketosis of cattle	Before and after parturition in cattle	Blood, urine and milk levels of ketone bodies during the transition period 3 weeks before and after parturition	Glucose IV. Propylene glycol and electrolyte solutions orally. Propylene glycol orally	Prepartum dietary management of energy intake

Pregnancy toxemia of sheep	Declining plane of nutrition in ewes in late pregnancy	Urinary ketones. Hypoglycemia. Metabolic acidosis and terminal uremia	Caesarean section or induction of parturition	Nutritional management of pregnant ewes to ensure a rising plane of nutrition in the second half of pregnancy.
Fatty liver of cattle	High-producing dairy cows overfed during the dry period. In well-conditioned beef cattle in late pregnancy when energy intake suddenly decreased	Ketonemia, ketonuria, hypoglycemia	Poor prognosis in severe cases. Fluid and electrolyte therapy, glucose IV, propylene glycol orally and insulin	Nutritional management of pregnant cows to avoid excessive weight gain. Avoid situations which reduce feed intake at time of parturition
Equine hyperlipidemia	Deranged fat metabolism. Pregnant or lactating middle-aged ponies, donkeys, and American miniature horses worldwide. Sporadic	Hyperlipidemia	Enteral or parenteral feeding, insulin, heparin. Treat underlying disease	Maintain optimal body condition. Prevent disease and nutritional stress in pregnancy
Post parturient hemoglobinuria	Dietary deficiency in high-producing dairy cows 2–4 weeks after calving. Copper deficient area. Cruciferous crops	Low serum inorganic phosphorus. Low PCV Hemoglobinuria	Whole blood transfusion Sodium acid phosphate IV. Dicalcium phosphate orally	Ensure adequate dietary phosphorous intake

Metabolic tests can now be used to predict displaced abomasum in dairy cattle.[4] In cows which develop a left-side displacement of the abomasum, mean NEFA concentrations begin to diverge from the mean in cows without LDA 14 days before calving, whereas mean serum β-hydroxybutyrate (BHBA) concentrations did not diverge until the day of calving.[4] Prepartum, only NEFA concentration was associated with risk of subsequent LDA. Between 0 and 6 days before calving, cows with NEFA concentrations ≥0.5 mEq/L were 3.6 times

more likely to develop a LDA after calving. For prospective application, among samples taken 4–10 days before expected calving, the optimum NEFA cutpoint remained 0.5 mEq/L. The sensitivity, specificity and likelihood ratio were 46%, 82%, and 2.6, respectively. Between 1 and 7 days post partum, retained placenta, metritis and increasing serum concentrations of BHBA and NEFA were associated with increased risk of subsequent LDA. The odds of LDA were eight times greater in cows with serum BHBA ≥1200 μmol/L. Cows with BHBA concentrations ≥1200 μmol/L were 3.4 times more likely to develop LDA. Serum calcium concentrations were not associated with LDA. In summary, strategic use of metabolic tests to monitor transition dairy cows should focus on NEFA in the last week prepartum and BHBA in the first week post partum.

The nutritional management strategies to optimize the metabolic health of transition cows has been reviewed.[6] During the transition period, dairy cows undergo large metabolic adaptations in glucose, fatty acid, and mineral metabolism.[6] The practical goal of nutritional management during this period is to support these metabolic adaptations. A 2-group nutritional strategy for dry cows to minimize overfeeding of nutrients during the early dry period but increase nutrient supply during the late dry period is now being recommended.[6] Increasing the amount of energy supplied through dietary carbohydrate during the prepartum period results in generally positive effects on metabolism and performance of transition cows. But the form of that carbohydrate (whether starch or highly digestible neutral detergent fiber) may be of lesser importance. Attempts to increase energy supply by feeding dietary fat sources or decrease energy expenditure by supplying specific fatty acids such as *trans*-10, *cis*-12 conjugated linoleic acid to decrease milk fat output during early lactation do not decrease the release of nonesterified fatty acids (NEFA) from adipose tissue.

In addition to nutritional management strategies to optimize health of the transition cow, certain feed additives are in use to reduce subclinical ketosis and reduce the incidence of displaced abomasum.[7] Monensin is a carboxylic polyether ionophore produced by a naturally occurring strain of *Streptomyces cinnamonesis*. Monensin exerts its many effects by shifting the microbial populations in the rumen. It changes the ratio of volatile fatty acids in the rumen, increasing propionic acid and reducing the molar percentages of butyric acid and acetic acid. Improved rumen propionic acid improves gluconeogenesis. When administered in controlled release capsule (CRC) 2–4 weeks before calving, monensin reduced the incidence of both clinical ketosis and displaced abomasum postcalving.[8] In a large dataset, monensin showed a trend for a 25% reduction in the incidence of retained placenta. Monensin improves energy metabolism which reduces the incidence of all three ‘energy

associated diseases', retained placenta, displaced abomasum and clinical ketosis. In Canada, the monensin-controlled release capsule (CRC) is approved as an aid in the prevention of subclinical ketosis in lactating dairy cattle. The capsule delivers 335 mg of monensin daily for 95 days.[9] Cows treated with the monensin CRC 3 weeks before calving had decreased NEFA and BHBA and increased concentrations of serum cholesterol and urea in the week immediately pre-calving. Monensin has no effect on calcium, phosphorus, or glucose in the pre-calving period. After calving, concentrations of phosphorus were lower and BHBA lower and cholesterol and urea higher in monensin-treated cows. The lower NEFA values indicate less fat mobilization and the higher cholesterol suggest greater lipoprotein export from the liver. The higher urea levels are thought to be due to a protein-sparing effect in the rumen, resulting in an increased supply of amino acids in the small intestine. There was no effect of treatment on NEFA, glucose, or calcium in the first week post-calving. Monensin treatment administered pre-calving significantly improved indicators of energy balance in both the immediate pre-calving and post-calving periods.

Abnormalities of the blood levels of the four macrominerals, calcium, phosphorus, magnesium, and potassium in the cow during the transition period are involved in subclinical hypocalcemia, clinical milk fever, hypomagnesemia, and acute hypokalemia.[10]

Knowledge of the complex behavioral needs of the dairy cow is essential in order to provide adequate housing during the transition period. In North American dairy herds, the flow of cows through the transition period often necessitates many changes of pens, which are disruptive to the social organization of cow groups. Stocking rates that exceed stall and feed bunk capacity place even greater challenges on the dairy cow at this time. Alternative strategies for cow grouping and improvements in pen and stall design which provide greater behavioral freedom for the dairy cow and improvements in health and productivity have been described.[11]

Management of the dairy cow at calving time is a major topic which requires that the veterinarian educate the animal attendants and owners.[12] The objective is to ensure the delivery of a viable, live calf and smooth transition of the cow without complications, from the dry period to the lactation period. The two major problems encountered at calving time are dystocia and perinatal mortality.

The diagnosis and treatment of dairy cows with periparturient diseases requires a program suited to the particular herd.[13] Particularly in large herds, there is a need for collaboration between the veterinarian, nutritionist, manager of the herd, and the animal attendants.

Specific procedures should be developed for each herd based on past experience with the problems of recently-calved cows, the facilities, the skills of the workers, the priorities of management, and the flow patterns of cows in the herd. Every effort must be made to prevent periparturient diseases in the cows. In general, diseases in the early post partum period originate in the feeding and management of the dry cow. Important principles include a protocol of grouping parturient cows according to the feeding program and handling facilities on the farm. Groups of cows can be screened for mastitis, visual evidence of illness, daily milk yield, body temperature, urine pH, palpated for evidence of metritis. Individual cows which have been identified by a screening method must be examined individually to make a diagnosis and decide on a treatment protocol based on the particular diagnosis.

The use of reliable records to monitor the health and production of dairy cows during the transition period is essential to evaluate the efficacy of programs at the farm level.[14] Monitors of transition cow management programs will assist in determining how well cows are prepared for milk production and good health in the coming lactation. Appropriate monitoring will focus on three areas: ***cows that die or are culled in early lactation, the productivity of the surviving cows in early lactation, and the rates of disease in the periparturient period.***

Cows which leave the herd in the first 60 days of lactation are usually culled because of disease or injury.[14] Removal rates and their causes can be a critical monitor of the efficacy of transition cow management programs. Measuring productivity and health of cows in early lactation involves monitoring peak milk, daily milk yields, first test mature equivalent 305-day projected milk, milk components at first Dairy Herd Improvement Association (DHIA) test day, milk fat percentage, ratios of test-day components, somatic cell count at first DHIA test day.[14] DHIA records also allow comparison of the performance of each cow in early lactation to her performance in the prior lactation. Comparisons can be made of the changes in somatic cell count between the last test of the prior lactation and the first test of the current lactation and mature equivalent 305-day difference from the prior lactation to the first test of the current lactation

Health and production records in dairy herds have traditionally emphasized reproductive events and treatments given. The records should capture the information about the common diseases which occur in most dairy herds.[14] The record system should be set up to:

- Monitor rates of well-defined disease events as a measure of the effectiveness of health and production programs and to aid problem solving

- Determine the clinical efficacy of treatments by monitoring retreatment rates for specific diseases
- Maintain an individual cow history record for cow-side use to enhance treatment decisions
- Measure compliance and consistency of implementation of the health program being used
- Reconcile pharmaceutical purchases with treatment protocol entries and to meet regulatory requirements on the use of pharmaceuticals in food animals
- Determine the costs of certain disease rates over achievable targets. The costs of specific diseases are compelling to most dairy herd producers. Good records can generate an incidence rate of common diseases. These costs include the immediate cost of treatment, the cost of the veterinarian's and herdsman's time and the cost of milk withheld from the market. For the majority of diseases of recently-calved cows, the cost per disease in the USA is about US$320.00 with a range from $150 to $450 as from the year 2001.

An adequate record system will allow producers and veterinarians to determine the differences between actual performance and benchmark performance and then determine the causes of the shortfall. The most important determinants of profitability on dairy farms are milk income and feed cost and the difference between milk income and feed costs is the return over feed index (ROF).[15] Many factors affect the ROF index. These include: three times daily milking, component percentages in the herd milk test, milk fat and protein percentages, use of an *E. coli* mastitis vaccine and use of monensin in the lactating cow diet.[15] One of the most important factors associated with profitability is milk production. From 80% to 95% of the income on dairy farms is derived from milk sales. Thus, it is critical that the producer, the veterinarian and other advisors collaborate to plan the animal health and production program which will result in the optimum ROF.

1615

1616

Other recent developments indicate that environmental and management factors can be manipulated to ease the transition into lactation.[16] The photoperiod, defined as the duration of light exposure an animal receives within a day, can be adjusted to produce dramatic effects on periparturient health and subsequent lactational efficiency. Increasing the frequency of milking in the immediate post partum period also produces persistent increases in milk yield and improvements in mammary health. In both techniques, evidence is

emerging to support the concept that alteration of prolactin sensitivity is the mechanism underlying health and production responses.

The prospect of 0 days for dry periods are being explored as a possible alternative management scheme in dairy herds.[17] In high-producing dairy cows, the dry period is influenced by parity and management practice. Multiparous cows that were continuously milked and treated with bovine somatotrophin (bST) demonstrated negligible production losses in the next lactation. First-calf heifers, however, demonstrated large reductions in milk yield.

29.1.3

Voluntary dry matter intake in periparturient dairy cattle

The factors affecting voluntary dry matter intake (VMDI) of lactating cattle are extremely important and have received much attention for many decades. The literature on the integration of metabolism and intake regulation in animals has been reviewed.[18] A substantial dip in VMDI is initiated in late pregnancy and continues into early lactation.[18] Pregnancy in dairy heifers has been shown to reduce VMDI from week 26 of pregnancy by 1.53% (approximately 0.17 kg) per week until 3 weeks before calving. In one study, in which the energy density of the diet remained constant during the last 168 days of pregnancy, a similar decline in energy intake during the last trimester of pregnancy both in heifers and lactating cows when diet energy was high (11.6 MJ of metabolizable energy/kg of DM), while the decline was much smaller or insignificant at lower energy densities (10.3 or 8.3 MJ of metabolizable energy/kg of DM).[18] The lowest VMDI occurs at calving. Post partum VDMI increases, but the rate varies widely. In cows given diets of constant composition, the milk yield typically peaks at 5–7 weeks post partum, while the maximum intake is reached between 8 and 22 weeks after calving. The increase in intake from week 1 post partum to time of peak intake varies from between 2% and 111%. These differences in intake are affected by the diet fed during lactation but may also depend on prepartum feeding by way of, at least in part, the influence and the degree of fatness and or body condition score (BCS) of the animal. Voluntary dry matter intake is considerably higher in multiparous cows compared with primiparous cows. The intake capacity of primiparous cows calving at an age of 2 years is only about 80% of that of multiparous cows in the first part of lactation. The normal pattern of intake may be severely influenced by disease states. Both clinical and subclinical infections are known to substantially reduce appetite and performance.

The dip in VMDI has traditionally been attributed to physical constraints such as the enlarging uterus but this role may be overemphasized. The dip coincides with changes in

reproductive status, fat mass and metabolic changes in support of lactation. A number of metabolic signals may have a role in intake regulation. These signals include nutrients, metabolites, reproductive hormones, stress hormones, leptin, insulin, gut peptides, cytokines and neuropeptides such as neuropeptide Y, galanin and corticotrophin-releasing factor.[18]

During late pregnancy and lactation, energy requirements increase considerably. Fetal energy requirements on day 250 of pregnancy have been calculated at 2.3 Mcal/d for Holstein cows. During lactation, energy requirement is increased to 26 Mcal net energy in cows producing 30 kg milk/day. Major changes in metabolism occur to cope with this increase in nutrient requirements. On a diet high in energy density, pregnant heifers will have a relatively high plasma concentration of glucose and a relatively low concentration of NEFA. Post partum, the concentration of NEFA is high while glucose is reduced. These changes reflect the large need for glucose and nutrients by the mammary gland and that dairy cows increase the use of lipid as a source of energy to support lactation. The NEFA begins to rise 2–3 weeks before calving and peaks at calving or during the first week of lactation. Glucose increases during the last week before calving and drops abruptly post partum to reach a minimum of 1–3 weeks into lactation. Post partum changes in the plasma concentration of BHBA are generally opposite those of glucose.

29.1.4 Immunosuppression during the transition period

In addition to the adaptations in classical metabolism which occurs during the transition period, cows during this period undergo a period of reduced immunological capacity during the periparturient period.[19] The immune dysfunction is broad in scope, affects multiple functions of various cell types and lasts about 3 weeks prior to calving until about 3 weeks after calving. Cows during this period are more susceptible to mastitis. The etiology of periparturient immunosuppression is multifactorial and not well understood but seems to be related to physiologic changes associate with parturition and the initiation of lactation and to metabolic factors related to these events. Glucocorticoids are immunosuppressants, are elevated at parturition and have been postulated to have a role in periparturient immunosuppression.

The effects of parturition on cytoplasmic glucocorticoid expression (GR) in neutrophils and the correlation of the expression with serum cortisol concentration and total leukocyte count and neutrophil counts in periparturient cows has been examined.[20] Neutrophils from periparturient cows had a 49% reduction in GR expression at calving, compared with GR expression 2–4 weeks before calving and 39% reduction, compared with neutrophils from

cows in mid-pregnancy. The reduction in neutrophil GR expression is detectable 1 week before calving and most severe at calving and 24 h after calving. Multiparous cows have prolonged GR down-regulation of their neutrophils compared with primiparous cows which may be associated with a higher incidence of mastitis in older cows. Serum cortisol concentrations and total leukocyte and neutrophil counts were significantly increased at calving and returned to baseline value by 24 h after calving. Thus, a cortisol-induced neutrophil GR down-regulation and neutrophil migration dysfunctions occur in periparturient dairy cows. There is impaired expression of adhesin molecules and decreased migration capacity of blood neutrophils. Rapid recruitment of neutrophils into newly infected mammary tissue is the key immunologic defense against mastitis-causing pathogens in ruminants.

Experimentally, nonesterified fatty acids in vitro significantly reduces immunosuppressiveness of mononuclear cells of ewes which may be associated with the impairment of cell-mediated and humoral immunity in sheep and cattle with ketosis.[21]

1616
1617

Because vitamin E is a fat-soluble membrane antioxidant which enhances the functional efficiency of neutrophils by protecting them from oxidative damage following intracellular killing of ingested bacteria, the parenteral administration of vitamin E has been explored for the prevention of peripartum diseases such as retained placenta, metritis, and clinical mastitis. Only cows with marginal vitamin E status (serum α-tocopherol $<2.5\times10^{-3}$) 1 week before calving will have a reduction in the risk of retained placenta following a subcutaneous injection of 3000 IU of vitamin E.[22] In cows with an adequate level of serum vitamin E there was no reduction and primiparous animals were most likely to benefit from vitamin E 1 week before parturition. The associations between peripartum serum vitamin E, retinol and β-carotene in dairy cattle and disease risk indicated that an increase in α-tocopherol of 1 μg/ML in the last week prepartum reduced the risk of retained placenta by 20%, whereas serum NEFA concentrations ≥0.5 mEq/L tended to increase the risk of retained placenta by 80%. In the last week prepartum, a 100 ng/mL increase in serum retinol was associated with a 60% decrease in the risk of early lactation clinical mastitis.[23]

29.1.5

Diseases of lactation

In the next phase of the production cycle, parturition is followed by the sudden onset of a profuse lactation which, if the nutrient reserves have already been seriously depleted, may further reduce them to below critical levels and clinical metabolic disease then occurs. The essential metabolite which is reduced below the critical level determines the clinical

syndrome which will occur. Most attention has been paid to variations in balances of calcium and inorganic phosphates relative to parturient paresis; magnesium relative to lactation tetany; blood glucose and ketones and hepatic glycogen relative to ketosis; and, potassium relative to hyperkalemia on cereal grazing, but it is probable that other imbalances are important in the production of as yet unidentified syndromes.

The vast majority of production diseases of dairy cows occur very early in lactation. At this time, the cow is producing milk at a rate which is substantially less than her maximum. In terms of rate, high and low milk yielding cows are producing rather similar amounts at this time. However, in terms of acceleration, the change in milk yield per day, it is highest immediately after calving.

During the succeeding period of lactation, particularly in cows on test schedules and under the strain of producing large quantities of milk, there is often a variable food intake, especially when pasture is the sole source of food and instability of the internal environment inevitably follows. The period of early lactation is an unstable one in all species. Hormonal stimulation at this stage is so strong that nutritional deficiency often does not limit milk production and a serious drain on reserves of metabolites may occur.

29.1.5.1

Recombinant bovine somatotrophin.

Recombinant bovine somatotrophin (rBST) is a synthetically derived hormone that may be identical to naturally occurring bovine growth hormone, or slightly modified by the addition of extra amino acids. The product was approved in the USA in 1993 and its use began commercially in 1994 in dairy herds to increase milk production.[24] A meta-analysis of the effects of rBST on milk production, animal health, reproductive performance and culling has been done in Canada and the drug was not approved for use. Recombinant bovine somatotrophin was found to increase milk production by 11.3% in primiparous cows and 15.3% in multiparous cows; although there was considerable variation between studies. While some statistically significant effects on milk composition (percentage of butterfat, protein, and lactose) were found, they were all very small. Treatment increased dry matter intake by an average of 1.5 kg/d during the treatment period and dry matter intake remained elevated on into the first 60 days of the subsequent lactation. Despite the increase in dry matter intake, treated animals had lower body condition scores at the end of the treatment period and the reduced scores persisted through until the start of the subsequent lactation. Recombinant bovine somatotrophin increased the risk of clinical mastitis by approximately 25% during the treatment period but there was insufficient data

to draw firm conclusions about the effects of the drug on the prevalence of subclinical intramammary infections. Use of rBST increased the risk of a cow failing to conceive by approximately 40%. For cows which did conceive, there was no effect on services per conception and only a small increase in average days open. Use of the drug had no effect on gestation length, but the information about a possible effect on twinning was equivocal. Cows treated with rBST had an estimated 55% increase in the risk of developing clinical signs of lameness. There appeared to be an increased risk of culling in multiparous cows. Use of the drug in one lactation period appeared to reduce the risk of metabolic diseases (particularly ketosis) in the early period of the subsequent lactation. The reproductive effects of the drug could be controlled by delaying its use until the cows were confirmed pregnant.

In 1998, an expert panel appointed by the Canadian Veterinary Medical Association at the request of Health Canada, found a number of legitimate animal welfare concerns associated with the use of rBST. In 1999, Health Canada announced that it would not approve the use of rBST for sale in Canada. The Royal College of Physicians and Surgeons of Canada Expert Panel on Human Safety of rBST found no biologically plausible reason for concern about human safety if rBST were to be approved for sale in Canada.

In 1999, a working group from within the Scientific Committee on Animal Health and Animal Welfare of the European Commission presented a more extensive report which summarized similar results and engaged substantive discussion of animal welfare from the points of view of physiologists and epidemiologists. It concluded that rBST should not be used in dairy cattle. In October 1999, the European Commission banned the use of and marketing of rBST in the European Union as of 1 January, 2000.[25] The animal welfare aspects of the use of rBST and the laws and ethical issues, data analysis, epidemiologic evaluation, and public policies involved for the different reasons made in the USA, Canada, and Europe with regard to the use of rBST in dairy cattle have been reviewed and discussed elsewhere.[25,26]

A comprehensive econometric model was developed to evaluate the potential effects of rBST approval on the Japanese dairy industry.[27] Simulation results indicate that rBST approval would accelerate structural change in Japan's dairy industry toward fewer, larger farms. Negative effects of rBST on farm income are projected to be more severe for smaller farms, because of higher costs, lower profit-earning ability, lower milk yields, and lower adoption rates of rBST. Larger farms would benefit from rBST adoption if milk

demand is maintained. However, if public health concerns about rBST induce significant milk demand decreases, even the largest farms' income and cow numbers would decrease. Thus, Japan's dairy industry could be caught in a double downward spiral of declining milk prices and production.

29.1.6 Breed susceptibility

The fact that some dams are affected much more by these variations than others is probably explainable on the basis of variations in internal metabolism and degree of milk production between species and between individuals. Between groups of cows, variations in susceptibility appear to depend on either genetic or management factors. Certainly, Jersey cows are more susceptible to parturient paresis than cows of other breeds and Guernseys seem to be more susceptible to ketosis. Even within breeds, considerable variation is evident in susceptibility between families. Under these circumstances, it seems necessary to invoke genetic factors, at least as predisposing causes.

1617

1618

29.1.7 Management practices

The management practices of most importance are housing and nutrition. In those sections of North America where cattle are housed during the winter and in poor pasture areas, ketosis is prevalent. In the Channel Islands, local cattle are unaffected by lactation tetany, whereas the disease is prevalent in the UK. In New Zealand, metabolic diseases are complex and the incidence is high, both probably related to the practice of having the cows calve in late winter when feed is poor and to the practice of depending entirely on pasture for feed and to the high proportion of Jerseys in the cattle population.

A knowledge of these various factors is essential before any reasonable scheme of prevention can be undertaken. It should also indicate that although the more common disease entities are presented in this chapter, there is high probability that a disturbance of more than one of the metabolites mentioned may occur simultaneously in the one animal and give rise to complex syndromes which are not described here. The disease entities dealt with must be considered as arbitrary points in a long scale of metabolic disturbances.

29.1.8 Occurrence and incidence of metabolic diseases

A knowledge of the etiological and epidemiological factors involved will help in understanding the occurrence and incidence of the various metabolic diseases.[28] Largely because of variations in climate, the occurrence of metabolic disease varies from season to

season and from year to year. In the same manner, variations in the types of disease occur. For example, in some seasons, most cases of parturient paresis will be tetanic; in others, most cases of ketosis will be complicated by hypocalcemia. Further, the incidence of metabolic disease and the incidence of the different syndromes will vary from region to region. Ketosis may be common in areas of low rainfall and on poor pasture. Lactation tetany may be common in colder areas and where natural shelter is poor. Recognition of these factors can make it possible to devise a means whereby the incidence of the diseases can be reduced.

The metabolic diseases, because of high prevalence and high mortality rate, are of major importance in some countries, so much so that predictive systems are being set up. Rapid analysis of stored feed samples, pasture and soil is commonly used in Europe and North America but the interesting development has been the recognition of ‘production diseases' and the consequent development of metabolic profile tests, particularly in the UK and in Europe.

29.2 Production diseases

The term ‘production disease' includes those diseases previously known as ‘metabolic diseases', such as parturient paresis (milk fever), hypomagnesemia, acetonemia, and perhaps some other conditions, all of which are attributable to an imbalance between the rates of **input** of dietary nutrients and the **output** of production. When the imbalance is maintained, it may lead to a change in the amount of the body's reserves of certain metabolites, or their ‘throughput' and sufficiently large changes in throughput. The generalization applies principally to the hypoglycemias (ketosis) and hypomagnesemias and partly to the hypocalcemias. In these diseases, output is greater than input either because of the selection of cattle which produce so heavily that no naturally occurring diet can maintain the cow in nutritional balance, or because the diet is insufficient in nutrient density or unevenly balanced. For example, a ration may contain sufficient protein for milk production but contains insufficient precursors of glucose to replace the energy excreted in the milk. While agreeing with the generalization on which the term ‘production disease' is based, we propose to continue to use the expression ‘metabolic disease' because of common usage.

29.2.1 Relationship between lactational performance and health of dairy cattle

The literature on the relationship between lactational performance and health in dairy cattle has been reviewed.[29] Based on a review of 11 epidemiological and 14 genetic studies there

was little evidence that high yielding cows have increased risk of dystocia, retained placenta, metritis, and left-side displacement of the abomasum. The results for periparturient diseases were inconsistent. While no phenotypical relationship between milk yield and the risk of ketosis and lameness was found, selection for higher milk yield will probably increase the lactational incidence risk for these diseases. Mastitis was the only disease where there was a clear relationship between milk yield and risk of infection. Continued selection for high milk yield will worsen this situation.

However, some authors claim that ‘Reviewing existing literature, even with structured literature selection, is inadequate to the task of elucidating the relationship between the lactational performance and risk of production diseases'.[29] The most notable feature of the literature evaluation is the large variability that exists between studies. This strongly suggests that there are important factors that need to be considered before meaningful conclusions concerning the relationship between lactational performance and risk of disease can be drawn.

29.2.2

COMPTON METABOLIC PROFILE TEST

Because of the emphasis on health management beginning in the 1970s, it became popular to explore methods of predicting the occurrence of metabolic disease in advance, so that control strategies could be considered and put into place. It was thought possible to predict the occurrence of production disease in a dairy herd by monitoring certain components of the blood on a regular basis. If the blood level fell below ‘normal', it was assumed that intake needed to be increased to compensate for the negative balance created by excessive output.

The Compton metabolic profile is based on the concept that the laboratory measurement of certain components of the blood will reflect the nutritional status of the animal, with or without the presence of clinical abnormalities. For example, a lower than normal mean blood glucose in a group of dairy cows in early lactation may indicate an insufficient intake of energy which may or may not be detectable clinically. On a theoretical basis, the ability of the laboratory to make an objective assessment of the input–output (nutrient–productivity) relationships is an attractive tool for the veterinarian engaged in providing a complete health management service to a herd. The test would theoretically be able to detect the qualitative and quantitative adequacy of the diet of cows expected to produce a certain quantity of milk or return to estrus within a desirable length of time following parturition. A reliable test for the early diagnosis of nutritional deficiency or metabolic disease would be a major step

forward in attempting to optimize livestock production and obtain maximum yields at minimum costs.

Some of the literature on metabolic profile testing in dairy cows has been reviewed.[30–32] The use and interpretation of metabolic profiles in dairy herds in the Dairy Herd Health and Productivity Service (DHHPS) have been reviewed.[33]

1618

Methods are needed to monitor nutritional and metabolic status of dairy herds. The most 1619 valuable methods will be those which are sensitive enough to detect change before clinical or economic consequences are manifested. A major challenge in the application of metabolic profile testing is dealing with extraneous sources of variation. Successful management of extraneous variation requires sampling strategies based on animal grouping and testing of multiple animals. Larger herds may be more suitable because they are able to better design sampling strategies and to spread the costs of testing across more animals. In addition, the cost–benefit may be greater in larger herds because of the high cost of inadequate feeds and feeding programs. Statistical Process Control methods offer a unique approach to interpretation which may increase the usefulness of metabolic profiles.[30]

There was considerable interest in the test following its earlier descriptions which stimulated considerable field research. The results of the research have thus far indicated that the test may be useful only as an aid in the diagnosis of nutritional imbalance and production diseases. The results of the test are usually difficult to interpret without a careful conventional assessment of the nutritional status and reproductive performance of the herd and it appears doubtful that the test would reveal significant abnormalities which could not be detected using conventional clinical methods. There was considerable controversy about the practicality of the test. Because of costs of the test, the profile testing must be carefully planned with specific objectives. A regional diagnostic laboratory with automated analytical equipment should be available and this is often a major limiting factor. The test should not be undertaken unless normal values for each laboratory measurement are available from the population within the area. The results from the groups within the herd are compared with local population means. Metabolic profiles have also been suggested as an aid in the selection of superior individuals.

29.2.3 METABOLIC PROFILES FOR INDIVIDUAL COWS

The prediction of whether an individual cow is metabolically within normal range to undergo a stressful lactation at a high level of production would seem to be a useful undertaking. This could be particularly important under management conditions of heavy concentrate feeding,

lead feeding, or zero grazing or even indoor housing. There are no well-established protocols for conducting such profile tests. The ‘parturition syndrome', dealt with later under the ‘fat cow syndrome' is considered to be predictable by the estimation of blood levels of total cholesterol and glutamic oxalate transaminase. In pastured cattle in New Zealand, the test has been found to be ineffective. Similar tests conducted on individual cows using many serum enzymes and electrolytes as indicators have not proved to be useful if used on only one occasion.

29.2.3.1

Usefulness of metabolic profile testing

Metabolic profiles in dairy cows were used initially in Britain in the 1960s. Success was limited primarily by the unjustified expectation that all biochemical concentrations in the blood of cows would reflect nutritional intake and status at all times.[34] However, the practical value was found in the approach as an aid to nutritional management. Later, in the 1970s the approach was reassessed and reinstituted, culminating in a program for farmers evaluating health and productivity using metabolic profile testing as an integral part of a health management program involving a multidisciplinary approach. The system now depends on a team approach involving farmer, veterinarian, and agricultural adviser. The blood testing part, if useful information is to be obtained, depends critically on following a set of firm criteria for selection of small groups of typical cows within each herd, the timing of testing in relation to concentrate feeds, feed changes, and stage of lactation and the collection of other data about the cows such as body weight and condition, productivity and feeding. The successful approach has been to look, following specific times of nutritional change, at metabolite levels in strictly defined small representative groups of cows within each herd in conjunction with information on body condition and weight, milk performance, and feeding. Comparison with optimum values, the degree of variation from them and comparisons between groups within herds have allowed information about nutritional constraints on productivity to be made available to farmers more quickly and more specifically than by other means.

Most metabolic profile testing has been used in temperate climates. The effectiveness of the technique for identifying constraints on productivity in small herds in tropical and sub-tropical countries has been examined.[34] The study involved 13 projects with 80 cows in each, done in six Latin American, six Asian, and one southern European countries. Data were also collected on feeding, body condition score and weight change, parasitism, and reproduction. In Chile, Mexico, Paraguay, Philippines, Uruguay, and Venezuela, globulin levels were high in >17% of cows samples on each occasion. In Paraguay, 49% of cows

had high globulin levels at 2–3 months after calving. This suggests that inflammatory disease was present although this was not always investigated. In all countries except Mexico and Venezuela, high β-hydroxybutyrate levels before calving in many cows highlighted the presence of body condition loss in late pregnancy, an important potential constraint on productivity and fertility. Fewer cows had high BHB levels in lactation, whereas change in BCS and weight was more sensitive for measuring negative energy balance. Urea concentrations were low in only small numbers of cows suggesting that dietary protein shortages were not common. Albumin levels were low mainly in cows where globulin values were high and therefore did not provide additional information. In China, pregnant yaks over winter had high BHB and low albumin values, suggesting that they were seriously underfed. This resulted in a successful nutritional intervention in the following winter. Inorganic phosphorus values were within the reference range in most countries most of the time, suggesting, contrary to expectation, that this mineral was not commonly a constraint. In summary, the use of metabolic profile testing proved valuable in drawing attention to important potential constraints on productivity in dairy cows in tropical and subtropical environments and in confirming those which were not.[34]

Metabolic profile testing has been used for the prevention of periparturient diseases in dairy cows in Japan.[35] In herds with a high incidence of periparturient disease, low blood values of hematocrit, albumin, glucose, cholesterol, calcium, and magnesium were observed in the dry period. The values correctly diagnose malnutrition as the cause of the periparturient diseases. Following feeding management changes, there was a low incidence of these diseases and the metabolic profiles were normal indicating that feeding management had improved. Because the traditional metabolic profile test is difficult to apply to peripartum cows because they are in state of physiological abnormality and the results are difficult to interpret, doing a test every 10 days during the dry and lactation periods has been evaluated.[36] The criteria were interpreted by the deviations from the reference mean values of metabolites rather than the actual values. The body condition score, albumin, blood urea nitrogen, glucose, total cholesterol, non-esterified fatty acids, γ-glutamyl transpeptidase, and aspartate aminotransferase, fluctuated during the dry and early lactation periods and there were large changes in the hematocrit, blood urea nitrogen, total cholesterol, and magnesium and high nonesterfied fatty acids in herds with a high incidence of peripartum diseases.

1619

1620

The values of the variables which deviated from the reference values for the metabolic profile components were able to assess milk production and feeding which is a practical tool for auxiliary feeding evaluation.[37]

The Dairy Herd Health and Productivity Service (DHHPS) in the UK provides the opportunity for veterinarians to lead a multidisciplinary team which can monitor health, fertility, and production and can plan, when necessary, corrective action.[38] Metabolic profiling and body condition scoring found that at least a third of the cows sampled were mobilizing excessive fat during the transition from the dry period to early lactation. Improving both health and nutrition, before and after calving, would improve reproductive performance in many herds. A team approach, with farmers, veterinarians, nutritionists, and other advisors working together with well defined goals and objectives, is necessary if progress is to be made in improving reproductive performance. High milk yields cannot always be the excuse for suboptimal fertility.[38]

29.2.3.2

Biological and statistical basis for herd testing

The interpretation of herd-based tests for metabolic diseases is different from interpreting laboratory tests for metabolites from individual cows.[39] Test results from individual cows are interpreted by comparing the value to a normal reference range established by the laboratory that did the testing. Normal ranges are often derived by calculating a 95% confidence interval (or a similar statistic) of test results from 100 or more clinically normal animals.

Herd test results for metabolic diseases can be interpreted as either the mean test result of the subgroup sampled or as the proportion of animals above or below a certain cut point within the subsample. If a metabolite is associated with disease when it is above or below a biologic threshold (cut point) then it should be evaluated as a proportional outcome. For example, subclinical ketosis in dairy herds can be monitored by testing for β-hydroxybutyrate (BHBA) or other ketone bodies in blood or milk. Subclinical ketosis is a threshold disease and cows are affected only when ketone concentrations are elevated. Blood BHBA concentrations above 1400 μmol/L is the most commonly used cut point for subclinical ketosis. Early lactation cows with BHB concentrations above this cut point are a threefold greater risk to develop either clinical ketosis or displaced abomasum. Non-esterified fatty acids (NEFA) concentrations in blood are an indicator of negative energy balance in prepartum cows. Elevated NEFAs before calving are associated with increased risk for displaced abomasum after calving. A threshold above 0.400 mEq/L for cows between 2 and 14 days of calving is suggested as an appropriate cut point.

It is also necessary to determine the alarm level for the proportion of animals above or below the described cut point. The alarm level is determined from research results or

clinical experience. The suggested alarm level proportions for BHBA with a cut point of =1400 μmol/L is >10% and for NEFAs with a cut point of =0.400 mEq/L is >10%.

Herd-based testing is useful only when a sufficient number of cows within the herd are tested, which gives reasonable confidence that the results truly represent the entire population of eligible cows in the herd. The minimum sample size for herd-based tests with proportional outcomes is 12 cows. Cows to be sampled need to be selected from the appropriate eligible or at risk group.

The 'proper' use of metabolic profiles depends on care with the timing of blood tests, the selection of cows to be included and the collection and use of background information about the farm, feeding, and feeding system and physical state and performance of the cows.[40]

As of 2005, for 5 years the Dairy Herd Health and Productivity Service (DHHPS) in the UK have been using the metabolic profile approach as an aid to the management of dairy cow nutrition. Effectively the approach has been to '***ask the cows***' what they think of their nutrition – by following a set of 'rules' on timing, cow selection and the use of background information.[33] The involvement of a team approach at the farm, including private veterinarian and nutritional adviser, to put the findings in the correct context and to identify the appropriate responses has been vital. Data on health and fertility from many of these farms has also been collected.

29.2.3.3 ## Variables in dairy-herd metabolic profile testing

29.2.3.3.1 ### Energy balance

29.2.3.3.1.1 #### Non-esterified fatty acids (NEFAs)

Non-esterified fatty acids are a sensitive indicator of energy balance. They are useful for monitoring energy status of dry cows in the last month of gestation, when rapid changes in energy balance status may not be detectable from changes in body condition score.[31] High values of NEFAs indicate negative energy balance which occurs in animals which are inappetent for any illness.

The serum levels of NEFAs have been monitored in dairy cows as predictors of displaced abomasum.[41] In cows with LDA, mean NEFA concentration began to diverge from the mean in cows without LDA 14 d before calving, whereas mean serum

β-hydroxybutyrate (BHBA) concentrations did not diverge until the day of calving. Prepartum, only NEFA concentration was associated with risk of LDA. Between Day 0 and 6 days after calving, cows with NEFA concentration of ≥0.5 mEq/L were 3.6 times more likely to develop LDA after calving. Strategic use of metabolic tests to monitor transition dairy cows should center on NEFA. In the last week prepartum and BHBA in the first week post partum.[41] In another study, cows with plasma NEFA >0.3 mEq/L between 3 and 35 days before calving were twice as likely to subsequently have an LDA.[42] In cows with serum BHBA ≥1200 or 1400 μmol/L in the first week post partum the odds of LDA were three and four times greater, respectively, than in cows with BHBA below the cut points.[43]

29.2.3.3.1.2

Serum β-hydroxybutyric acid (BHBA)

Serum BHBA concentrations are affected by energy and glucose balance and are a less specific indicator of energy balance than plasma NEFA. High values are associated with reduced milk production, increased clinical ketosis and LDA and reduced fertility.[30] The gold standard test for subclinical ketosis is blood BHBA which is more stable ketone body than acetone or acetoacetate. Subclinical ketosis may start at serum concentrations above 1000 μmol/L. The alarm level for the proportion of cows above the cut-point of 1400 μmol/L has not been determined but it is suggested that no more than 10% subclinical ketosis should be tolerated in early lactation cows.[32] Serum concentrations of 1400 μmol/L or greater in the first 2 weeks post-calving was found to cause a three-fold greater risk for cows to subsequently develop either clinical ketosis or LDA.[44]

Between 1 and 7 days post partum, retained placenta, metritis and increasing serum concentrations of BHBA and NEFA were associated with increased risk of subsequent LDA. The odds of LDA were eight times greater in cows with serum BHBA = 1200 μmol/L were 3.4 times more likely to develop LDA.[41]

29.2.3.3.1.3

Blood glucose

Blood glucose concentrations are usually lower in early lactation and during the winter months; in early lactation, there is a heavy demand for glucose and during the winter the energy intake is likely to be lower than necessary to meet requirements. One major cause of variation in blood glucose may be the major fluctuations in daily feed intake. Investigations of feed intake of dairy cows on commercial farms have shown that

1620
1621

concentrate dispensers are commonly incorrectly adjusted and errors of more than 50% in feed intake are sometimes found. In situations of marginal energy imbalance, blood glucose concentration levels may be unreliable as an index of the adequacy of energy intake. Several factors may cause short-term changes in blood glucose. Blood glucose decreases at the time of milk secretion, which makes sampling time critical. Blood glucose may also be influenced by the chemical nature of the carbohydrate and physical form of the feed and the roughage content of the feed. In addition, elevation of blood glucose has been associated with excitement and low environmental temperature.

There is some conflicting evidence about the relationship between mean values of blood glucose of a lactational group and insufficient energy intake and reproductive inefficiency. In some work, there is an expected relationship between low blood glucose and an increased incidence of ketosis. In others, the relationship is not clear, however there was a more consistent relationship between the actual energy intake as a percentage of requirement and the plasma non-esterified fatty acids, but this finding was not sufficiently reliable to be useful. The mean plasma glucose concentrations within 3 days before or after first service of cows which conceived on first service was higher than that of cows which returned, but the difference was only approaching significance at the 5% level and it is doubtful whether this could be of practical value. Although free fatty acids are more sensitive than blood glucose as an indicator of energy status of the lactating cow, the excessive variability of this relationship during early lactation limits its usefulness. Free fatty acids begin to increase several weeks prepartum, peak at parturition and decrease gradually to normal levels after several weeks of lactation. Blood glucose levels follow a similar pattern; however, there may be a period in early lactation when blood metabolite levels and particularly free fatty acids, are not entirely responsive to energy intake, but are perhaps under additional hormonal regulation.

29.2.3.3.2

Protein nutrition and metabolism

29.2.3.3.2.1

Urea nitrogen testing to evaluate protein

Milk urea N (MUN) can be used as a management aid to improve dairy herd nutrition and monitor the nutritional status of lactating dairy cows. Urinary N (UN) excretion has been shown to have a positive linear relationship with MUN. Elevated MUN indicates excess protein has been fed to the dairy cow for her given level of

production. When adequate energy is in the diet of ruminants, both blood urea nitrogen and milk urea nitrogen have long been known to be indicators of their protein status. Increases in plasma urea concentration and ammonia occur primarily as a result of inefficient nitrogen utilization. An excess of rumen degradable protein results in an increase in the concentration of rumen ammonia, which is absorbed through the rumen wall and transported to the liver, where it is converted to urea. The catabolism of body protein for gluconeogenesis can also result in the production of ammonia, which is also converted to urea in the liver. Plasma urea has been the most commonly used blood constituent for monitoring protein status and intake. Urea moves passively from the blood into the milk and there is a close relationship between its concentrations in the two fluids. Thus, milk urea has been used as a non-invasive substitute for the measurement of the protein status and protein intake of ruminants. There is also a relationship between urinary nitrogen excretion (UN) and milk nitrogen (MUN). It has been estimated that when dietary energy remained unchanged, milk urea concentration increased by 12–18 mg/L for each additional 60 g of digestible crude protein fed to cows already receiving adequate protein.[45] Milk samples should be submitted to an accredited diagnostic laboratory for MUN analysis. The Azotest Strip, an on-farm dipstick test, lacks accuracy and is not recommended.[46]

The milk urea nitrogen target concentrations for lactating dairy cows fed according to National Research Council Recommendations have been evaluated.[47] Target N ranges from approximately 150 to 200 g/d. The target MUN concentrations are now 8.5–11.5 mg/dL for most dairy herds compared with the previous target concentrations of 12–16 mg/dL.[47,48] Milk urea, together with percentage milk protein is being used increasingly as an indicator of the dietary protein–energy balance. In many European countries and North American states and provinces, UREA analyses are available in Dairy Herd Improvement (DHI) programs. The somatic cell count did not lower UREA concentrations in quarters with elevated SCC.[49] The time of sampling can have a significant effect on UREA concentrations; the highest in the morning and the diurnal pattern was not influenced by intrinsic factors like parity, days post partum or daily milk yield.[49] The levels were significantly increased after refrigeration for 1 week.

Providing dairy farmers with information regarding their herd's MUN should result in more accurate feed management and change toward target values. A survey of dairy farmers in a region in Virginia and Maryland indicated that 89.5% did not routinely

use MUN prior to participating in the project, but most (88%) extension agents and nutritionists in the region recommended it. Providing MUN results and interpretive information to farmers changed feeding practices and subsequent MUN results.[50]

High milk yield in dairy cows is dependent on high intakes of dietary protein (17–19% crude protein) and energy. However, in the ruminant, high protein diets may be associated with reduced reproductive performance. In the UK, dairy cattle are housed over the winter months and turned out to graze in the spring. Spring turnout coincides with the first flush of new pasture growth which can contain very high levels of rapidly degradable protein. Many dairy herds in the UK experience a short-term fall in pregnancy rates at spring turnout. It has been suggested that the problem at turnout is worst on pastures heavily fertilized with nitrogenous fertilizers.

Several reviews of the literature have examined the effect of protein nutrition on reproduction in dairy cows. The reported effect of high nitrogen intake on fertility is inconsistent. Experimentally, the ingestion of a high level of degradable protein commencing 10 days before insemination in lactating dairy cows had no effect on reproductive performance of the lactating high yielding dairy cow.[51] The relationship between milk urea concentration and the fertility of dairy cows from 250 herds in the UK found no relationship between bulk milk urea concentration and fertility, or between changes in bulk milk urea concentrations and fertility.[45] Also, the relationship between the milk urea concentration 5 days after service and the fertility of individual cows was examined. There was no significant difference between the milk urea concentration of the cows which became pregnant and those that did not.

A meta-analysis of the literature evaluated the associations between dietary requirements for protein for dairy cattle, the metabolism of protein in cattle, factors influencing the degradability of protein in ruminant feeds, and factors influencing milk urea concentrations.[52] There are good correlations between dietary protein intake and rumen ammonia, blood urea, and milk urea concentrations. The effect of increasing dietary protein on milk production has been defined through feeding trials and modeling methods used to provide feeding standards. Ryegrass clover pastures provide feed in many of the temperate dairy regions of the world and for much of the year pasture crude protein may exceed 30%, of which a high proportion is rapidly degradable. High dietary protein intakes may have a negative effect on reproductive performance in lactating dairy cows, but the role of milk urea as a predictor of fertility needs further definition given the high conception rates in many Australasian dairy

herds.[52] High intakes of dietary protein may induce adaptations in urea metabolism and the negative relationship identified between high intakes of dietary protein and fertility for Northern Hemisphere dairy herds may not necessarily apply in Australasian dairy herds. Because of the potential for cows to adapt to high protein diets, the use of single milk urea determination on a herd will have limited value as an indicator of nutritional status and little value as a predictor of fertility.[52] The differing observations between various production systems indicate the need for careful consideration in applying recommendations for dietary protein management based on milk urea concentrations. Milk urea determinations may, however, have value, particularly when used in conjunction with other herd and nutritional data to assess the protein nutrition of dairy herds. It is highly unlikely that single or even serial determinations of milk urea in single cows or bulk tank milk will have a high predictive value for determining the risk of conception in the cow or herd.[52]

29.2.3.3.3

Serum albumin

Serum albumin is related to protein status of the animal. Lactation stage has a substantial effect on serum albumin. Animals should be grouped into dry cows, early lactation (1–10 weeks) and later lactation. Minimal values for dry cow means are from 2.9 to 3.1 g/dL, for recently calved cows from 2.7 to 2.9 g/dL and 3.0 to 3.2 g/dL for cows in later lactation.

29.2.3.3.4

Hematology

29.2.3.3.4.1

Hematocrit (packed cell volume)

The hematocrit can be used as a general reflection of health. In most dairy herds, a low hematocrit may be a reflection of suboptimal energy and protein nutrition. Mean values of packed cell volume (PCV), hemoglobin and serum iron are consistently higher in non-lactating cows than in lactating cows. Parasitism causing blood loss will result in a low hematocrit. The hematocrit varies with lactation stage, being highest in dry cows and lowest in early lactation. Cows should be grouped by lactation stage.

29.2.3.3.5 Mineral nutrition

29.2.3.3.5.1 Serum inorganic phosphorus

Serum inorganic phosphate levels tend to fall following long-term insufficient dietary intake and hyperphosphatemia may occur in cattle grazing on highly fertilized pasture.

29.2.3.3.5.2 Serum calcium

Serum calcium levels vary only within narrow limits and are not sensitive indicators of input–output balance. However, abnormally low levels in late pregnancy indicate a dangerous situation.

29.2.3.3.5.3 Serum magnesium

Serum magnesium levels are usually low during the winter months and subclinical hypomagnesemia exists in many herds, especially pregnant beef cattle. This can be converted into clinical hypomagnesemia with a sudden deprivation of feed or a sudden fall in environmental temperature. Supplementation of the diet with magnesium salts is protective.

29.2.3.3.5.4 Serum sodium

Low levels of serum sodium occur in early lactation in cows grazing on summer pastures without supplementation with salt. Levels down to 135 mmol/L may be associated with depraved appetite and polydipsia and polyuria.

29.2.3.3.5.5 Serum potassium

Serum potassium levels have been difficult to interpret because the levels of the electrolyte in serum are not necessarily indicative of potassium deficiency. Its normal serum concentration is much more variable than sodium and its average concentration in roughages of all kinds is nearly always in excess of requirements; any abnormalities are usually in the direction of excess.

29.2.3.3.6 Timing of blood tests

29.2.3.3.6.1 In relation to feed changes

As changes in the diet of ruminants require changes in the character of rumen activity, blood samples for metabolic profiles should not be done until 2 weeks after a major change and activity has had time to adapt. Minor changes such as an increase in the quantity of an existing component or in access to the same ration do not require a wait of more than 7–10 days. Changes in forage type, such as turnout to pasture, housing, or the introduction of silage require the full 2 weeks. The same applies for introduction of concentrates or of a new type of concentrate.

29.2.3.3.6.2 In relation to feeding

There can be changes in biochemical values in blood associated with feeding. These are most marked in cows receiving all their concentrate ration at milking time. In such cases, 2 h should be allowed to elapse after milking before blood sampling. In circumstances where the major part of the concentrate input is mixed with the forages and is available for most of each 24 h, the timing of tests in relation to feeding is less critical. If lower yielding mid lactation cows are included (see later), their results can be used as a check to see if there is an effect of feeding on the biochemical values in the blood samples. Cows should not be separated at milking time and confined for hours without access to food waiting for blood sampling as this can also affect the results.

29.2.3.3.6.3 In relation to calving pattern and seasonal feeding changes

The cow in early lactation is the most important because what happens to her in the first few weeks after calving has the major influence on her subsequent productivity, including her future fertility efficiency. Therefore, blood sampling for metabolic profiles should be carried out at the beginning of each new calving season, with the first cows checked so that the majority can benefit from the information derived.

Of equal importance is the need to test as soon as possible after the introduction of a new ration, so that evaluation of the cows' biochemistry can be made available as quickly as possible, i.e. ***what the cows, the end users, think of the ration.***

Therefore planning of metabolic profile tests needs to be done in advance and should take in to account both expected calving pattern and feed changes. Without planning along these lines, time may be lost and productivity with it.

29.2.3.3.7

Selection of cows

Picking appropriate cows for blood sampling is very important. This is because some of the metabolites looked at, particularly those relating to energy balance, can quickly return to the optimum range as cows adapt themselves, including their productivity, to a nutritional constraint. It is possible for cows to experience a significant energy deficit in the first 2–3 weeks of lactation because of intake problems, lose excessive body condition, perhaps modify their milk yield, and have their subsequent fertility efficiency suppressed but yet still arrive at 4 weeks calved with all biochemical measurements within the optimum ranges. This is because the common appetite constraint of the new calved has worked its way out and there is plenty of food available for lower performance than anticipated. If blood is sampled at 4 weeks calved or longer, a farmer could see thin, under-producing cows with poor fertility but with nothing abnormal about their biochemistry. Thus, the farmer would be entitled to feel the metabolic profile test was of no value. However, if those cows had been blood sampled at 14 days calved instead of 27, the blood results would have been quite different and would have identified the nutritional constraint on productivity.[53]

The ***'Rules' for metabolic profiling of dairy cattle*** recommend sampling from the following groups:

1622

1623

- Early lactation (EL): between 10 and 20 days of lactation
- Mid lactation (ML): between 50 and 120 days of lactation
- Dry period (D): between 7 and 10 days of calving.

Individual variations in biochemical values are such that single cows should not be tested. ***Groups of no less than five should be sampled.*** They should not be picked at random but rather should be typical, average cows of their stage of lactation. Cows with extremes of performance – either very high or very low – should not be selected. Cows with problems should also not be included because the type of analysis carried out is not designed to clarify individual problems. It is important to make all this clear to farmers in advance because they cannot be expected to appreciate the limitations of the analyses

made. Experience in the Dairy Herd Health and Productivity Service in the UK[33] suggests that selecting cows for metabolic profiles may be best done by the veterinarian in advance of the test after looking at the calving and production records. If there is a specific concern such as a poor conception rate, farmers may expect only cows which have failed to conceive to be sampled. This hardly ever delivers helpful information as any nutritional constraints have by then been compensated for and blood biochemical values are usually within optimum ranges. The best approach may be to include such cows as the mid-lactation group.

29.2.3.3.7.1

Early lactation group (EL)

The definition used for this group is most critical for the reasons given in the previous paragraph. Since the original Compton metabolic profile where high yielding cow was used as the definition, the importance of this group has become increasingly apparent. The definition also has had to be changed to take into account changes in farm practice. The way cows are fed now – total mixed rations, increased out of-parlor concentrate feeding – has reduced the time after calving by when they can adapt themselves to an unsatisfactory diet. ***To be sure of detecting the presence of an energy constraint in particular, blood sampling should be carried out between 10 and 20 days calved*** – less than 10 days and the yield is still too far below peak for the test to be a realistic one for early lactation performance; more than 20 days and some cows will be thin, unproductive and subfertile but have compensated for their nutrition and they may have normal blood metabolite values.

29.2.3.3.7.2

Mid-lactation group (ML)

Some cows which are passed the period of peak yield and so passed the greatest period of potential nutritional stress should always be included. ***They should be between 50 and 120 days calved*** so that they are still relatively high yielding. This group provides a within-herd comparison with the early lactation cows. Without this it is very difficult to distinguish between problems caused by constraints on intake of food or protein and energy content; to identify changes in biochemical values caused by mistiming of tests in relation to feeding or by oddities in the diet such as silage with a high butyric acid content; and to make judgments on concentrate/forage usage within the herd.

29.2.3.3.7.3

Dry cow group (D)

As the dry period is so important to the success of the following lactation, blood sampling to make sure nutrition is adequate is essential. However, the nature of the measurements which can be made means that primarily ***cows in the last 7–10 days of pregnancy should be sampled.*** Cows tested with longer to go than that tend to have normal measurements of energy balance even though they can still get in to difficulty. This is because the period of greatest risk is when the volume of the pregnant uterus increases to the point that it can seriously inhibit food intake. It follows that, in a seasonal calving herd, the first dry cows which come in to these last 7–10 days ought to be blood sampled, so that the information can be used for the benefit of the others still to come in to the maximum risk period.

Blood sampling a group of dry cows with 1 month or longer to go to calving at the same time can sometimes provide a useful within herd comparison with respect to energy balance. It may also identify the presence of dietary protein inadequacy – specifically rumen degradable – in the early part of the dry period.

In the DHHPS program, a majority of farms do metabolic profiles 3–4 times a year at critical times as a check '***ask-the-cows-what-they-think'*** exercise. Thus metabolic profiles as part of a pro-active preventive health and productivity programme. Some of the larger farms may do more than 10 tests a year to cover feed changes and to check on the success of any corrective action.

In the DHHPS program, a standard DHHPS metabolic profile includes analysis on blood plasma for β-hydroxybutyrate (BHB), glucose, non-esterified fatty acid (NEFA), urea-nitrogen (urea N), albumin, globulin, magnesium, and inorganic phosphate.[33] Analyses for copper and glutathione peroxidase (GSHPx) are done on approximately one-third of samples received and thyroxine T4 on even fewer. Biochemical analysis is performed using two Bayer Opera auto-analysers, with standard internal controls. It also employs an independent, external quality control system. Derivation of optimum metabolite values are summarized in Table 29.2. They are BHB <1.0 mmol/L in cows in milk, <0.6 mmol/L in dry cows; glucose >3.0 mmol/L; NEFA <0.7 mmol/L in cows in milk and <0.5 mmol/L in dry cows; ureaN >1.7 mmol/L; albumin >30 g/L; globulin <50 g/L; magnesium >0.7 mmol/L; inorganic phosphate >1.3 mmol/L; copper >9.2 μmol/L; glutathione peroxidase (GSHPx) >50 U/g HB; thyroxine T4 >20 nmol/L.

Table 29.2 Metabolic profile parameters in cattle. Optimum values

Parameter	SI units
Butyrate Milkers	Below 1.00 mmol/L
Dry cows	Below 0.60 mmol/L
Plasma glucose	Over 3.00 mmol/L
NEFA Milkers	Below 0.70 mmol/L
Dry cows	Below 0.40 mmol/L
UreaN	1.70–5.00 mmol/L
Albumin	Over 30.00 g/L
Globulin	Under 50.0 g/L
Magnesium	0.80–1.30 mmol/L
Phosphate (inorganic)	1.40–2.50 mmol/L
Copper	9.40–19.00 μmol/L
Thyroxine T4 (iodine)	Over 20.00 nmol/L
GSHPx (selenium)	Over 50units/g Hb

29.2.3.3.7.3.1

Energy.

The data in Table 29.3 uses only the cows fitting precisely the definitions of EL, ML, and D. It shows that, overall, an average of 30% EL cows had metabolite results reflecting satisfactory energy status as did 61% of ML and 43% of D. In both EL and ML groups, glucose is the metabolite most commonly outside its optimum range, followed by BHB and NEFA. The percentage of NEFA values above optimum is low in ML cows. The most common finding is high BHB and low glucose in the same cow. In tests showing most cows in an EL group with results like that, there is usually one or two with high NEFAs as well. Some EL cows show only low glucose or only high NEFA. Where low glucose only predominates in EL cows, ML cows often show the same picture.

29.2.3.3.7.3.2

Protein.

UreaN results in Table 29.3 show that the EL stage is more vulnerable to low values than later in lactation, even though the cows would have been on the same diets in

virtually every case. In fact an even greater average percentage[51] in 1361 cows blood sampled between 0 and 9 days after calving over the 5 years showed low ureaN.

The proportion of low ureaN results in D cows is high (Table 29.3). In addition to the category shown of 10 days or less before calving, 4335 cows were sampled at more than 10 days prepartum over the 5 years and 22% of them had low ureaN values too.

1623

1624

Table 29.3 Annual (April–March) percentages outside optimum ranges of metabolite results in blood plasma in adult dairy cows[33]

	Early lactation (EL) (10–20 days calved)					Mid lactation (ML) (50–120 days calved)					Dry (D) (7–10 days prepartum)				
	1999/00	2000/01	2001/02	2002/03	2003/04	1999/00	2000/01	2001/02	2002/03	2003/04	1999/00	2000/01	2001/02	2002/03	2003/04
β-hydroxybutyrate (BHB)	19.5	16.6	22.3	22.9	17.5	11.2	10.5	14.3	10.6	9.6	34.5	24.7	38.5	28.5	22.7
Glucose	46.0	48.7	43.1	49.0	59.3	21.8	25.9	14.5	22.5	25.4	23.9	27.3	21.7	27.3	33.8
Non-esterified fatty acid (NEFA)	19.1	22.2	24.9	27.4	28.0	0.6	2.1	1.8	2.7	3.1	10.8	15.0	14.2	13.0	14.8
One or more energy metabolite per cow	65	70	67	72	78	34	39	32	40	44	59	57	63	46	63
Urea-nitrogen (UreaN)	0.8	17.3	18.3	16.7	16.7	4.4	6.4	6.0	5.3	5.6	18.4	20.4	20.2	20.8	22.3
Number of cows	1295	1421	1248	1285	1530	914	1066	849	1179	1494	1160	1379	1253	1358	1543

Results outside the optimum ranges for albumin (0.6%), magnesium (2.5%), inorganic phosphate (1.0%), copper (10%), GSHPx (3%) are relatively uncommon. Thyroxine T4 analysis was carried out in 836 samples on specific request and only 3% were below optimum.

29.2.3.3.8

Background information

So that full value can be obtained by the farmer from the metabolic profile approach, information about the cows and the farm should accompany the blood samples to the laboratory. This should include cow identification; last calving date for milkers/expected for dry cows; body weight – by calculation from heart-girth measurement with a weighband pulled to a constant 5 kg tension is the best, because it is not affected by gutfill and usually most practical, because no mechanical weighing device/crush is required; body condition score by a palpation method; current daily milk yield; expected current daily milk yield; lactation number; daily supplementary feed intakes; daily

estimated forage intakes; analytical description of feeds and current herd milk solids percentages. It is useful to have information on herd size, breed, feeding systems, and health and fertility. A note of what concerns the farmer has, if any, should also be made.

29.2.3.3.9

Interpretation of results at the farm

Circumstances where the diagnosis of a nutritional constraint from blood samples is clearly correct, but the cause(s) are unclear from a distance and could be many, are common. Therefore it is very important that a final interpretation of what is not working and what are the best and most economic solutions ought to be made at the farm with the information from the laboratory to hand. Farm advisory visits should be made as soon as the results are available and discussions made, including farm staff and any other advisers involved. Experience in the DHHPS suggests that such a team approach produces a more balanced strategy and is more beneficial than each party working in isolation.

29.2.3.3.9.1

Written advice

Any advice given should be recorded concisely in writing and copies given to all participants on the farm. This ensures that the agreed path is followed, keeps a record, and ensures that the fee is for something tangible.

29.2.3.3.10

Body condition score (BCS)

Managing body reserves is critical for successful cow management and requires an accurate assessment of the cow's ‘condition'. Body condition scoring is an important aspect of metabolic diseases of farm animals. Body weight alone is not a valid indicator of body reserves, as cows of a specific weight may be tall and thin or short and fat. The energy stores may vary by as much as 40% in cows of similar body weight, which emphasizes the futility and inaccuracy of relying on body weight alone as an index of cow condition. In addition, because tissue mobilization in early lactation occurs as feed intake is increasing, decreases in body tissue weight can be masked by enhanced fill of the gastrointestinal tract, so that body weight changes do not reflect changes in adipose tissue and lean tissue weight.[54]

There is a strong positive relationship ($r^2 = 0.86$) between body condition score (BCS) and the proportion of physically dissected fat in Friesian cows. Therefore, the visual or tactile (palpation) appraisal of the cow's body condition score provides a good

assessment of body fat reserves, ignoring, or minimizing the effect of, frame size and intestinal contents. Most animal and dairy scientists acknowledge successfully manipulating BCS as an important management factor, influencing or having a relationship to animal health, milk production, and reproduction in the modern dairy cow. For example, cows which lost 0.5–1.0 point in BCS between parturition and first service achieved pregnancy rate to first service of 53%, while those losing >1.0 point achieved a rate of 17%.[55] In a seasonal pasture-based system for Holstein–Friesian cows, it is necessary to maintain a BCS at ≥2.75 during the breeding season. Body condition score is important in achieving good reproductive performance. Loss of body condition between calving and first service should be restricted to 0.5 BCS to avoid a detrimental effect on reproductive performance.[55]

BCS is a subjective method of assessing the amount of metabolizable energy stored in fat and muscle (body reserves) on a live animal. BCS in dairy cows is done using a variety of scales and systems. This method involves palpating the cow to assess the amount of tissue under the skin. Scoring body condition and assessing changes in the body condition of dairy cattle have become strategic tools in both farm management and research. BCS is being researched worldwide. But international sharing, comparing, and use of data generated are limited because different BCS systems are used. There is difficulty in interpreting the literature because of variability in the way authors apply scoring methods. In the USA, Canada, and Ireland a 5-point BCS system is used for dairy cows, whereas Australia and New Zealand use 8- and 10-point scales, respectively.[56] The following scoring method is recommended for the 0–5 scale. The BCS chart adapted from Edmonson et al. appears in Figure 29.1.[54]

29.2.3.3.10.1

Score: 0

- Condition: Very poor
- Tailhead area: Deep cavity under tail and around tailhead. Skin drawn tight over pelvis with no tissue detectable in between

1624

1625

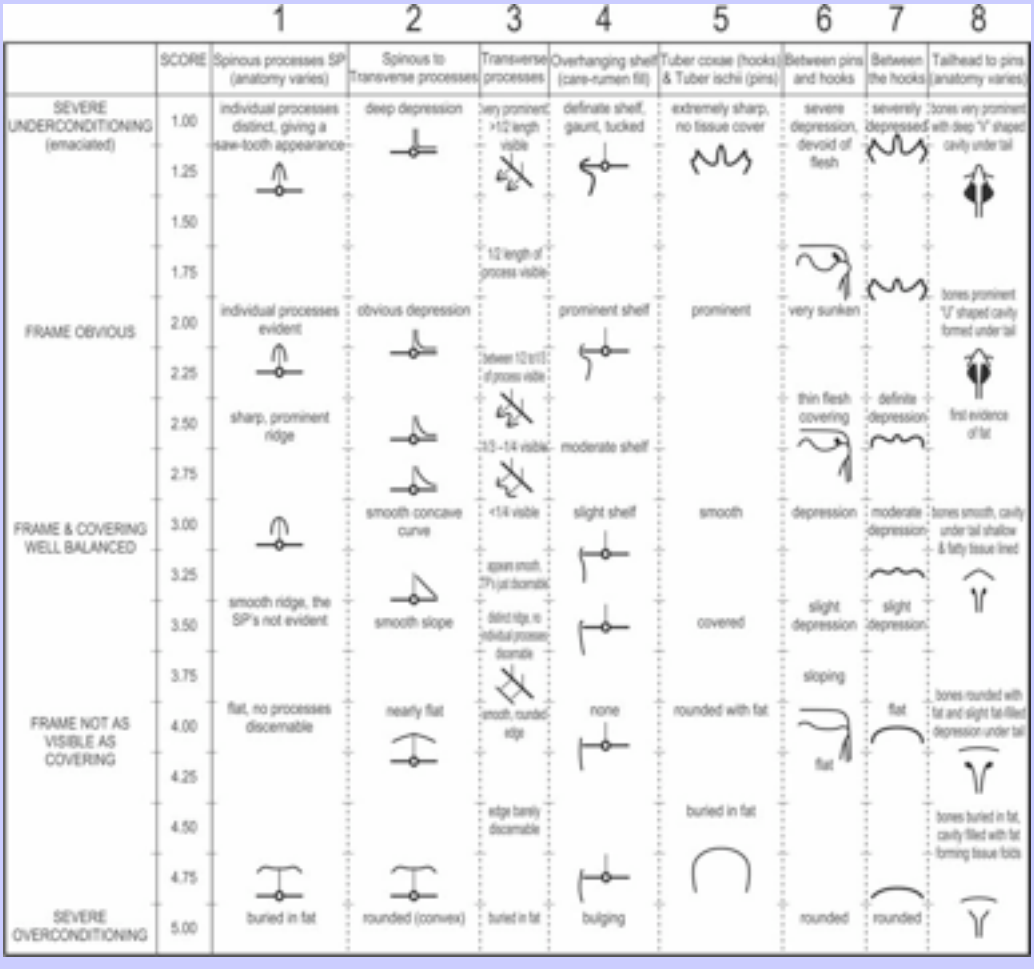
- Loin area: No fatty tissue felt. Shapes of transverse processes clearly visible
- Animal appears emaciated.

29.2.3.3.10.2

Score: 1

- Condition: Poor
- Tailhead area: Cavity present around tailhead. No fatty tissue felt between skin and pelvis, but skin is supple
- Loin area: Ends of transverse processes sharp to touch and dorsal surfaces can be easily felt. Deep depression in loin.

Fig. 29.1 Body condition scoring chart adapted from Edmonson et al. (1989).



29.2.3.3.10.3

Score: 2

- Condition: Moderate
- Tailhead area: Shallow cavity lined with fatty tissue apparent at tailhead. Some fatty tissue felt under the skin. Pelvis easily felt
- Loin area: Ends of transverse processes feel rounded but dorsal surfaces felt only with pressure. Depression visible in loin.

29.2.3.3.10.4

Score: 3

- Condition: Good
- Tailhead area: Fatty tissue easily felt over the whole area. Skin appears smooth but pelvis can be felt
- Loin area: Ends of transverse processes can be felt with pressure but thick layer of tissue dorsum. Slight depression visible in loin.

29.2.3.3.10.5

Score: 4

- Condition: Fat
- Tailhead area: Folds of soft fatty tissue present
- Patches of fat apparent under skin. Pelvis felt only with firm pressure
- Loin area: Transverse processes cannot be felt even with firm pressure. No depression visible in loin between backbone and hip bones.

29.2.3.3.10.6

Score: 5

- Condition: Grossly fat
- Tailhead area: Tailhead buried in fatty tissue. Skin distended. No part of pelvis felt even with firm pressure
- Loin area: Folds of fatty tissue over transverse processes. Bone structure cannot be felt.

29.2.3.3.11

Relationships among international body condition scoring

The New Zealand 10-point scale was compared with the scoring systems in the USA, Ireland, and Australia by trained assessors.[35] Cows were assessed visually in the USA and Australia and in Ireland, cows were assessed by palpating key areas of the cow's body. Significant positive linear relationships were found between the New Zealand 10-point scale and the other scoring systems. The relationship between the 10-point BCS scale used in New Zealand and Ireland and the USA are summarized in Table 29.4.

1625

Table 29.4 Relationship between the 10-point BCS scale used in New Zealand and the 5-point BCS scale used in Ireland and the USA, and the 8-point scale used in Australia

New Zealand	USA	Ireland	Australia
1.0	1.83	1.21	2.74
1.5	1.98	1.41	3.01

29.2.4

PARTURIENT PARESIS (MILK FEVER)

A disease of cattle, sheep, and goats occurring around the time of parturition and caused by hypocalcemia and characterized by weakness, recumbency, and ultimately shock and death.

1626

1627

29.2.4.1

Synopsis

29.2.4.1.1

Etiology

Hypocalcemia just before or after parturition.

29.2.4.1.2

Epidemiology

Adult dairy cows in third parity and older; 4–9% with low case fatality. Most commonly within 48 h after calving but also occurs several weeks before or after. Occurs in beef cattle in epidemics. Occurs in sheep and goats in epidemics usually following stressors. Prepartum diets high in calcium.

29.2.4.1.3

Signs

Three progressively worse stages including the following signs:

- Anorexia
- Ruminal atony
- Scant feces

- Inactivity
- General muscular weakness leading to sternal recumbency with lateral kink of neck
- Circulatory collapse with collapsed veins and weak pulse
- Dry muzzle
- Mental depression
- Hypothermia
- Weak heart sounds
- Dilated and sluggish pupils
- Ruminal stasis and bloat
- Lateral recumbency
- Tachycardia
- Death in few to several hours.

29.2.4.1.4

Clinical pathology

Hypocalcemia, hypophosphatemia, variable serum magnesium. Increased creatine phosphokinase (CPK) and aminotransferase (AST) due to ischemic muscle necrosis.

29.2.4.1.5

Necropsy findings

No specific lesions. Ischemic muscle necrosis of large muscles of pelvic limbs because of prolonged recumbency.

29.2.4.1.6

Differential diagnosis list

29.2.4.1.6.1

Cattle

Metabolic and nutritional disease

- Hypophosphatemia

- Hypomagnesemia
- Downer cow syndrome
- Fat cow syndrome
- Carbohydrate engorgement.

29.2.4.1.6.2

Toxemias

- Peracute coliform mastitis
- Aspiration pneumonia
- Acute diffuse peritonitis.

29.2.4.1.6.3

Injuries to pelvis and pelvic limbs

- Maternal obstetrical paralysis
- Dislocation of coxofemoral joint.

29.2.4.1.6.4

Sheep and goats

- Pregnancy toxemia
- Enterotoxemia.

29.2.4.1.7

Diagnostic confirmation

Hypocalcemia and response to treatment with calcium borogluconate.

29.2.4.1.8

Treatment

Calcium borogluconate IV. Calcium chloride in oral gel.

29.2.4.1.9

Control

Dietary management to reduce prepartum intake of calcium. Dietary cation–anion difference program. Calcium gel oral dosing before calving, at calving and 12 and 24 h after calving. Parenteral vitamin D and analogs.

29.2.4.2

ETIOLOGY

A depression of the levels of ionized calcium in tissue fluids is the basic biochemical defect in milk fever. A transient period of subclinical hypocalcemia (total plasma calcium <1.9 mmol/L) occurs at the onset of lactation caused by an imbalance between calcium output in the colostrum and influx of calcium to the extracellular pool from intestine and bone. The onset of lactation results in a sudden large demand on the calcium homeostasis. A cow producing 10 kg of colostrum (2.3 g of Ca/kg) will lose 23 g of calcium in a single milking. This is about nine times as much calcium as that present in the entire plasma calcium pool of the cow.[1] Calcium lost from the plasma pool must be replaced by increasing intestinal absorption and bone resorption of calcium. During the dry period, calcium requirements are minimal at about 10–12 g/d. At parturition, the cow must mobilize about 30 g or more of calcium into the calcium pool per day. Hypocalcemia occurs in spite of apparently adequate function of the parathyroid and vitamin D endocrine system and most cows adapt within 48 h after calving by increases in plasma concentrations of parathyroid hormone and 1,25-$(OH)_2$D vitamin at the onset of the hypocalcemia and mobilize calcium by increasing intestinal absorption and bone resorption.

About 5–20% of adult cows are unable to maintain plasma calcium and consequently develop severe hypocalcemia (total plasma calcium, 1.0–1.4 mmol/L) or clinical milk fever which requires treatment.[2]

29.2.4.3

EPIDEMIOLOGY

29.2.4.3.1

Occurrence

29.2.4.3.1.1

Cattle

The disease occurs most commonly in high-producing adult lactating dairy cattle. Lactating beef cows are affected but less commonly.

29.2.4.3.1.1.1

Age.

Mature dairy cows are most commonly affected in the 5–10-year age group, although rare cases have been observed at the first and second calvings. The

hypocalcemia at calving is also age related and most marked in cows at their 3rd to 7th parturition; it is infrequent at the first parturition.

29.2.4.3.1.1.2

Breed.

There are differences in susceptibility between the breeds but the differences are small.[2] Field observations have for many years suggested that Jersey's are most susceptible but the reported 33% was observed in a sample compared with 9.6% incidence in other breeds may be associated with the older age of many Jersey cows. The disease in beef cattle breeds occurs either in individual cows or in herd outbreaks.[3]

29.2.4.3.1.1.3

Individual cows.

Individual cows and to some extent families of cows, are more susceptible than others; the disease tends to recur at successive parturitions. The heritability of susceptibility to milk fever and hypocalcemia has been assessed as insignificant; in several breeds examined it was of the order of 6–12%. Complete milking in the first 48 h after calving, as opposed to normal sucking by a calf, appears to be a precipitating factor. Several studies have reported that the incidence of milk fever is positively associated with the level of milk production.[2]

29.2.4.3.1.1.4

Time of occurrence.

In cattle, milk fever occurs at three main stages in the lactation cycle. Most prepartum cases occur in the last few days of pregnancy and during parturition but rare cases occur several weeks before calving. Some cases will occur a few hours before parturition or at the time of parturition when the attendant expects the cow to calve and the second stage of parturition does not occur because of uterine inertia due to hypocalcemia. Most cases occur within the first 48 h after calving and the danger period extends up to about the 10th postpartum day. Up to 20% of cases can occur subsequent to the 8th day after calving. In such cases the declines in serum calcium and phosphorus levels are smaller and the increases in serum magnesium levels are greater than in parturient cows. The clinical signs are also less severe and there are fewer relapses after treatment. Occasional cases occur 6–8 weeks after parturition (mid-lactation). Such cases are most often recurrences of the disease in highly susceptible cows which were affected at calving. Undue fatigue and

excitement may precipitate such attacks and there is a special susceptibility at estrus. In the latter case, the depression of appetite by the elevation of blood estrogen levels may be a significant factor.

The plasma levels of phosphorus also decrease and the plasma levels of magnesium increase as occurs in cows at the time of parturition. Hypocalcemic episodes lasting 1–2 days may occur two or three times with a periodicity of about 9 days. These cows are referred to as ‘calcium cyclers' and the magnitude of the cycling was increased by feeding cows 200 g/d of 1,25-dihydroxyvitamin D for 5 days around the time of parturition. Fluctuations in the intestinal absorption of calcium during this period may be the cause of calcium cycling. Subclinical hypocalcemia is of major significance because it inhibits reticulorumen motility, which affects appetite and exacerbates the negative energy balance already existing in the cow in 1st month of lactation.

Episodes of subclinical hypocalcemia occur in up to 50% of adult cows during the first few weeks of lactation. It is suggested that these calcium cyclers are animals whose calcium homeostatic mechanisms have not adapted well enough. 1627 1628

29.2.4.3.1.1.5

Stressors.

Starvation for 48 h also causes severe depression of serum calcium levels and this may be of importance in the production of hypocalcemic paresis in this species at times other than in the postparturient period. Pregnant beef cattle may develop hypocalcemic paresis during the winter months when they are fed on poor-quality roughage; within a group of such cows the less aggressive ones may suffer selective malnutrition. The disease has also occurred in beef cows affected with diarrhea of undetermined etiology. As another explanation of the heightened susceptibility of cows at estrus, a possible depression of the degree of ionization of calcium under the influence of increased serum estrogens is suggested. However, there were no significant differences in total serum calcium or plasma ionized calcium values in cows from 48 h before and after estrus.

Hypocalcemic syndromes in ruminants are also observed at times other than related to parturition. Thus, it can be part of an early or mild overeating of fermentable carbohydrate. The IV administration of certain aminoglycosides, especially neomycin, elihydrostreptomycin and gentamicin, may cause a reduction in the degree of ionization of serum calcium and a syndrome similar to milk fever. Oral

dosing with zinc oxide (40 or 120 mg Zn/kg BW) as a prophylaxis against facial eczema in ewes causes a serious fall in serum calcium levels 24 h later. Caution is recommended with the use of these drugs in parturient cows.

29.2.4.3.1.2

Sheep and goats

In sheep, the disease commonly occurs in outbreaks in groups of ewes exposed to forced exercise, long-distance transport, sudden deprivation of food and grazing on oxalate-containing plants or green cereal crops. These circumstances commonly precipitate outbreaks of hypocalcemic paresis in sheep, mature ewes are the most susceptible, particularly in the period from 6 weeks before to 10 weeks after lambing. Up to 25% of the flock may be affected at one time. The disease also occurs in young sheep up to about 1 year old, especially when they graze green oats, but also when pasture is short in winter and spring, as in southeast Australia. The disease is manifested by paresis but in the rest of the flock poor growth, lameness and bone fragility can be detected. A sudden deprivation of feed or forced exercise of ewes can cause marked depression of the serum calcium levels. However, ewes are in a susceptible state in early lactation because they are in negative calcium balance. In late lactation a state of positive balance is due to a low rate of bone resorption. There is an unexplained occurrence of hypocalcemia in sheep fed on hay when they are supplemented with an energy-rich concentrate which increases their calcium intake. Some of the concentrates fed to ewes in feedlots contain supplementary magnesium as a prevention against hypomagnesemia, which may affect calcium absorption and precipitate hypocalcemia in susceptible ewes. Another occurrence in ewes is at the end of a drought when the pasture growth is lush and very low in calcium content. The incidence may be as high as 10% and the case-fatality rate 20% in ewe flocks in late pregnancy or early lactation.

Hypocalcemia in sheep depresses endogenous glucose production and in late pregnancy in combination with hyperketonemia, facilitates the development of pregnancy toxemia.[4]

In goats, a depression in serum levels of calcium and phosphorus occurs similar to that in cows but in ewes no such depression occurs at lambing and the intervention of a precipitating factor appears to be necessary to further reduce the serum calcium level below a critical point.

Milking goats become affected mostly during the 4–6-year age group. Cases occur before and after kidding, some later than 3 weeks after parturition. Clinical syndromes are identical to those in cows, including the two stages of ataxia and recumbency. Serum calcium levels are reduced from normal levels for parturient does of 9.4–3.6 mg/dL (2.35–0.9 mmol/L).

29.2.4.3.2

Morbidity and case fatality

Several epidemiological studies of milk fever have shown an incidence risk of 5–10%, calculated either as the lactational incidence or incidence per cow year.[2] Generally the disease is sporadic but on individual farms the incidence may rarely reach 25–30% of high-risk cows. In Victoria, Australia, 85% of dairy herds calve in the spring and the incidence of milk fever ranges from 2% to 5%.[5] With early treatment relatively few deaths occur in uncomplicated cases but incidental losses due to aspiration pneumonia, mastitis, and limb injuries may occur. From 75% to 85% of uncomplicated cases respond to calcium therapy alone. A proportion of these animals require more than one treatment, either because complete recovery is delayed, or because relapse occurs. The remaining 15–25% are either complicated by other conditions or incorrectly diagnosed.

29.2.4.3.2.1

Subclinical hypocalcemia.

Subclinical hypocalcemia (total plasma calcium <1.9 mmol/L) occurs in dairy cattle during the first few weeks of lactation. The incidence of subclinical hypocalcemia based on measurement of blood calcium around the time of calving and later in lactation ranges from 23% to 39%.[2] Up to 50% of aged cows may be unable to maintain plasma calcium above the lower normal limit (2.18 mmol/L) as defined by the 99% confidence interval of plasma calcium concentrations in cows outside the first month of lactation. In New Zealand, up to 40% of apparently normal cows may have subclinical hypocalcemia during the first 12 days of lactation.[6] Up to 33% of cows grazing pasture in New Zealand may have subclinical hypocalcemia on the day of calving.

In the USDA National Animal Health Monitoring System Dairy study of 2002, 1446 cows from 480 dairy herds in 21 states were sampled within 48 h of parturition. Subclinical hypocalcemia increased with advancing age and represented 25.3%, 43.9%, and 57.8% of first, second, and third lactation cows, respectively.[7] Of the

groups studied, 38.7% were on a DCAD program and the incidence of hypocalcemia was significantly less in those animals on the DCAD program. Also, with normal calcium levels had lower serum NEFAs indicating that their energy status was better than those with hypocalcemia.

29.2.4.3.3

Risk factors

The literature on the risk factors associated with milk fever has been reviewed.[2]

29.2.4.3.3.1

Animal risk factors

Serum calcium levels decline in all adult cows at calving due to the onset of lactation. Serum calcium levels decline to lower levels in some cows than in others and it is this difference which results in the varying susceptibility of animals to parturient paresis.[6] First-calf heifers rarely develop milk fever because while some degree of hypocalcemia occurs during the first few days of lactation, they are able to adapt rapidly to the high demands of calcium for lactation. With increasing age, this adaptation process is decreased and results in moderate-to-severe hypocalcemia in most adult cows. The adaptation mechanism is directly related to the efficiency of intestinal absorption of calcium, which decreases with increasing age.

29.2.4.3.3.1.1

Calcium homeostasis.

Three factors affect calcium homeostasis and variations in one or more of them may be important in causing the disease in any individual:

1. Excessive loss of calcium in the colostrum beyond the capacity of absorption from the intestines and mobilization from the bones to replace. Variations in susceptibility between cows could be due to variations in the concentration of calcium in the milk and the volume of milk secreted.

2. Impairment of absorption of calcium from the intestine at parturition.

3. Mobilization of calcium from storage in the skeleton may not be sufficiently rapid to maintain normal serum levels. The calcium mobilization rate and the immediately available calcium reserves are sufficiently reduced in cows in later pregnancy to render them incapable of withstanding the expected loss of calcium in the milk. In older cows, bone resorption makes only a minor

contribution to the total rate of calcium mobilization at parturition and is therefore of minor importance for the prevention of periparturient hypocalcemia. Osteoblasts are the only type of bone cell to express the 1,25-$(OH)_2D$ receptor protein and the decrease in the numbers of osteoblasts with increasing age could delay the ability of bone to contribute calcium to the plasma calcium pool.[1]

It was once postulated that failure to secrete sufficient levels of parathyroid hormone or 1,25-dihydroxyvitamin D was the primary defect in cows which developed milk fever. While it is accepted that the calcium homeostatic mechanisms, regulated by parathyroid hormone and 1,25-dihydroxyvitamin D, fail to maintain normal blood calcium concentrations resulting in severe hypocalcemia, the nature of the endocrine defect is not well understood. It was also once thought that calcitonin, a hormone which inhibits bone calcium resorption was a cause of milk fever but this has not been demonstrated in cows with milk fever.[1] Recent studies have shown that the secretion of parathyroid hormone and the production of 1,25-dihydroxyvitamin D is similar in most cows with or without milk fever.[1] However, about 20% of cows treated for parturient paresis experience relapsing episodes of hypocalcemia which require further treatment. These cows fail to produce adequate levels of 1,25-dihydroxyvitamin D at the onset of lactation.[6] Both relapsing and non-relapsing cows develop the same degree of hypocalcemia and secondary hyperparathyroidism, but production of 1,25-dihydroxyvitamin D is about two-fold greater in non-relapsing cows than relapsing cows. Following treatment of parturient hypocalcemia with calcium salts IV and restoration of ruminal and intestinal motility, non-relapsing cows establish calcium homeostasis over the next 3–4 days by increasing intestinal absorption of calcium which is activated by a sufficient level of 1,25-dihydroxyvitamin D. In relapsing cows, even when rumen and intestinal motility are restored after treatment, hypocalcemia and paresis are likely to occur because of insufficient plasma 1,25-dihydroxyvitamin D. These cows may remain in this stage of prolonged hypocalcemia for several days and only after a few days and several repeated treatments with calcium will the plasma levels of 1,25-dihydroxyvitamin D increase to an adequate level to maintain calcium homeostasis. It is also unlikely that the parathyroid hormone-related protein in the colostrum of milk fever cows is involved in the disease.[6]

Tissue 1,25-dihydroxyvitamin D receptor concentrations decline with age, which renders older cows less able to respond to 1,25-dihydroxyvitamin D.[1] The intestinal 1,25-$(OH)_2$D receptor numbers decline with age in the cow and thus the older cow is less able to respond to the hormone and will take longer to adapt intestinal calcium absorption mechanisms to meet lactational demands for calcium.[6]

A perplexing situation in dairy practice is the recently calved cow with peracute coliform mastitis which may also be mildly hypocalcemic and have some of the clinical signs of milk fever. The *Escherichia coli* endotoxin given IV depresses serum calcium and phosphate levels so that coliform mastitis may contribute to a degree of hypocalcemia in individual cows. However, there is no evidence that cows with peracute coliform mastitis require calcium therapy similar to that used in typical milk fever.

29.2.4.3.3.1.2

Body condition score (BCS).

A high BCS increases the risk of milk fever. The odds ratio of milk fever with a BCS >4/5 on the first milk recording day after calving was 4.3[2] and cows with milk fever had a postpartum pre-disease 12 kg higher body weight compared with healthy cows indicating an increased risk of milk fever due to higher body weight. Cows with subclinical hypocalcemia in the winter period had significantly higher mean body weight over the 60 days post partum than normocalcemic cows but the effect was not significant in cows calving during the summer months.

29.2.4.3.3.2

Dietary and environmental risk factors

Several dietary factors of the pregnant cow during the prepartum period (last 4 weeks) can influence the incidence of milk fever in cattle.

29.2.4.3.3.2.1

Dietary calcium.

Feeding more than 100 g of calcium daily during the dry period is associated with an increased incidence of milk fever.[2] A 500 kg cow requires only about 31 g of calcium to meet daily maintenance and fetal demands in late gestation. When a cow is fed a high calcium diet (>100 g Ca/d), its daily requirement for calcium can be met almost entirely by passive absorption of dietary calcium. The active transport of calcium from the diet and bone calcium resorption mechanisms are homeostatically

depressed and become quiescent. As a consequence, at calving, the cow is unable to use bone calcium stores or intestinal calcium absorption mechanisms and is susceptible to severe hypocalcemia until these mechanisms can be activated, which may take several days.

Feeding prepartum diets containing a low concentration of calcium prevents milk fever by activating calcium transport mechanisms in the intestine and bone prior to parturition, thus allowing the animal to adapt more rapidly to the lactational drain of calcium. Feeding diets high in calcium just before parturition may also lower the incidence of milk fever by increasing the absorption of calcium. This will provide sufficient calcium to overcome the relative lack of calcium from bone resorption which results from a high calcium intake.[9]

In sheep, hypocalcemia may occur in pregnant ewes fed a calcium-deficient diet over a prolonged period. A high dietary level of magnesium in late pregnancy may also predispose to hypocalcemia in pregnant ewes but this has not been documented. Ewes fed a diet with a fixed cation excess (82.3 mEq/100 g DM) had higher urine pH and lower urine calcium concentrations, lower blood ionized calcium concentrations after an overnight fast and tended to develop hypocalcemia more rapidly after an ethylenediamine tetra-acetate (NaEDTA) infusion. This suggests that a dietary fixed cation–anion balance may be a risk factor for hypocalcemia in pregnant ewes.

29.2.4.3.3.2.2

Dietary phosphorus.

Prepartum diets high in phosphorus (>80 g P/d) also increases the incidence of milk fever and the severity of hypocalcemia.[10] High dietary levels of phosphorus increase the serum level of phosphorus which is inhibitory to the renal enzymes that catalyze production of 1,25-$(OH)_2D$, which when decreased reduce the intestinal calcium absorption mechanisms prepartum.

29.2.4.3.3.2.3

Dietary cation-anion difference (DCAD).

The anion–cation dietary difference exerts a strong, linear effect on the incidence of milk fever. The dietary cation – anion balance in the prepartum diet may be more important than the level of dietary calcium as a risk factor for milk fever.[2] Prepartum diets high in cations such as sodium and potassium are associated with an increased

incidence of milk fever, while diets high in anions, especially chloride and sulfur, are associated with a decrease in the incidence of the disease. Alkaline diets containing an excessive concentration of sodium and potassium can result in an increased incidence of the disease. Most forages such as legumes and grasses are high in potassium and are alkaline. Metabolic alkalosis predisposes cows to milk fever. Under most circumstances the alkalosis is induced by the potassium in the diet.[11] The addition of anions to the diet of dairy cows prior to parturition effectively reduced the incidence of milk fever by inducing a metabolic acidosis which facilitates bone resorption of calcium.

1629 1630

The quantitative relationship between feed cations and anions predict the alkylogenic or acidogenic response in the animal or the DCAD. The difference between the number of cation and anion particles absorbed from the diet determines the pH of the blood. The cation–anion difference of a diet is commonly described in milliequivalents (mEq) per kg (dry matter) DM (mEq/kg DM) feed. This value is calculated as: DCAD = $(Na^+ + K^+) – (Cl^– + S^–)$.[10] Calcium, magnesium and phosphorus content of feeds will also affect acid–base status but are considered to have minor importance in the calculation of the DCAD. The DCAD equation describes how the ions contained in the feeds affect the metabolic processes in the body by the absorption and further metabolism and thereby causing changes in the systemic acid–base status. Systemic acidification induced by anionic supplementation affects the function of the parathyroid (PTH) hormone. The major effect of systemic acidification is to cause an increased response to PTH which results in increased retention of calcium and enhanced mobilization of calcium from bone. A total DCAD in the range of – 100 to – 200 mEq/kg feed DM is effective in controlling milk fever. Most natural feedstuffs fed to dairy cows will, on a molar basis, have a surplus of sodium and potassium compared with chloride and sulfur. A composite ration, with a negative DCAD value, is difficult to achieve in commercial dairy herd conditions.

A meta-analysis of 75 feeding trials designed to study the nutritional risk factors for milk fever in dairy cattle found that the prepartum dietary concentrations of S and dietary anion–cation balance [(Na + K) – (Cl + S)] were the two nutritional factors most strongly correlated to the incidence of milk fever.[2] Dietary S acts as a strong anion and reduces the risk of milk fever and increasing the dietary S concentrations lowers the odds ratio of developing milk fever. Increasing dietary Na and crude protein increased the odds ratios, but to a lesser extent.

The incidence of milk fever has been decreased by the addition of chloride and sulfur in excess relative to sodium and potassium in the prepartum diet of Holstein cows. High anion diets increase the plasma levels of 1,25-$(OH)_2D$ prior to parturition, activating intestinal calcium absorption and possibly bone calcium resorption mechanisms prior to onset of lactation.[10] Monitoring the pH of urine is a sensitive method for assessing the risk of milk fever.[12] The urine pH within 48 h prior to parturition has a significant negative correlation with serum calcium and inorganic phosphorus. The sensitivity, specificity, positive and negative predictive values of urine pH test prior to parturition, using a cut off level of above pH 8.25, were 100%, 81%, 55%, and 100%, respectively.[12]

29.2.4.3.3.2.4

Effects of milk fever and subclinical hypocalcemia.

There are several consequences of milk fever and subclinical hypocalcemia including its economic importance and the disease complications which may occur.

29.2.4.4

ECONOMIC IMPORTANCE

Unlike many years ago, the economic losses from milk fever have decreased because calcium borogluconate is an effective treatment which many owners can administer. Significant costs are associated with veterinary intervention and losses due to complications. However, while veterinarians now treat fewer cases of uncomplicated milk fever, there may be an increase in cases which are complicated by factors other than hypocalcemia.

The literature on the effects of clinical milk fever and subclinical hypocalcemia is difficult to interpret because of the complex relationships between milk production, parity of lactation, breed of cattle, epidemiological methods used, management systems being used, and the reproducibility of the clinical observations and the accuracy of the recording systems used.[2] In general, there is insufficient information available to document the consequences of milk fever and subclinical hypocalcemia. A summary of several consequences which have been examined follows here.

29.2.4.4.1

Milk fever relapses.

Milk fever cases which need repeat treatment because of relapses increase the costs.

29.2.4.4.2

Downer cow complications.

The downer cow syndrome associated with milk fever cases which fail to respond within a few hours and remain recumbent for several hours or several days before subsequently standing, or die, or are euthanized represents an important cause of economic loss because of treatment costs, long-term care costs, loss of milk production and loss of the value of the animal. Acute mastitis due to environmental pathogens is a common complication of prolonged recumbency in downer cows associated with milk fever. Some studies have found downer cows had a probability of 35% of being culled in the first 150 days of lactation and a relative risk of being culled of 29.2.[2]

29.2.4.4.3

Dystocia and reproductive disease.

Hypocalcemia at the time of parturition can result in uterine inertia which may cause dystocia and uterine prolapse. In general, there is an increased risk of dystocia associated with milk fever whether the farmer or the veterinarian attends to the dystocia.[2]

29.2.4.4.4

Retained placenta.

Several studies have found an increased risk of retained placenta following milk fever.[2]

29.2.4.4.5

Metritis.

A few studies have found an indirect relationship between milk fever and subsequent metritis.[2]

29.2.4.4.6

Milk production.

There is no reliable evidence that the occurrence of milk fever or subclinical hypocalcemia in cows which recover following treatment affects milk production in the subsequent lactation. Some studies have found a limited effect, no effect or even positive effect of milk fever on milk production.

29.2.4.4.7

Mastitis.

An odds ratio of 8.1 or mastitis has been estimated; for coliform mastitis an odds ratio of 9.0 and for acute clinical mastitis a relative risk of 1.5 following milk fever have been found.[2]

29.2.4.4.8

Displacement of abomasum.

Odds ratios ranging from 2.3 to 3.4 for left side displacement of the abomasum occurring in dairy cows with hypocalcemia at parturition have been estimated.[2]

29.2.4.4.9

Ketosis.

Studies on the occurrence of ketosis following milk fever have found relative risks or odds ratios ranging from 1.3 to 8.9 and using all the confidence intervals the relative risks/odds ratios range from 1.1 to 15.3.[2]

29.2.4.4.10

Body weight.

A temporary drop in body weight occurs in cows with milk fever but there is no long-term effect. In cows with subclinical hypocalcemia in early lactation there may be some weight loss compared with cows with normal levels of calcium.[2]

29.2.4.4.11

Culling.

There may be an increased probability of culling cows which have had milk fever because of the complications or direct or indirect consequences associated with the disease.[2] There is some evidence of culling cows in early lactation because of milk fever but not in late lactation.

29.2.4.5

PATHOGENESIS

The literature on the role of acid–base physiology on the pathogenesis of parturient hypocalcemia and the application of the DCAD in theory and practice has been reviewed.[11]

29.2.4.5.1

Hypocalcemia

Plasma calcium concentration is normally maintained between 2.1 and 2.6 mmol/L (8.5 – 10.4 mg/dL). Almost all dairy cows will experience subclinical hypocalcemia, <1.8 mmol/L (7.5 mg/dL) within 24 h after calving. In some cows, the hypocalcemia is more severe, <1.25 mmol/L (5 mg/dL) causing neuromuscular dysfunction resulting in clinical milk fever. Without treatment, levels may continue to decline to about 0.5 mmol/L (2 mg/dL) which is usually incompatible with life.[13]

1630

1631

Hypocalcemia is the cause of the signs of typical ‘milk fever'. Atony of skeletal muscle and plain muscle are well-known physiological effects of hypocalcemia. Hypophosphatemia and variations in levels of serum magnesium also occur and have secondary roles. In experimental hypocalcemia in cattle, there is:

- A marked reduction in the stroke volume and cardiac output
- A 50% reduction in arterial blood pressure
- A reduction in ruminal and abomasal tone and motility.

Total plasma calcium concentration at calving is not significantly related to fat and protein-corrected milk yield at any lactation period.[14]

In rare cases, pathological changes in the myocardium of hypocalcemic parturient cows have been reported.[9] The cows were hypocalcemic, recumbent, with tachycardia, arrhythmia, and dyspnea and failed to respond to calcium therapy, however, the cause of the lesions was not determined. The plasma natriuretic peptide concentrations were elevated indicating myocardial injury.[15]

29.2.4.5.1.1

Experimental hypocalcemia

The literature of Na_2 EDTA induced hypocalcemia has been reviewed.[16] A standardized flow rate of 1.2 mL/kg per hour of a 5% solution of Na_2 EDTA until recumbency, results in changes in plasma ionized calcium, total calcium, inorganic phosphate and magnesium comparable with spontaneous milk fever.[17] Induced hypocalcemia in cows results in a depression of frequency and amplitude of rumen contractions as early as 1.0 mmol/L of ionized serum calcium well before any clinical signs of hypocalcemia are detectable and while feeding behavior and rumination are

still normal.[18] The induction of subclinical hypocalcemia in cows results in a linear decrease in feed intake and chewing activity as the plasma ionized calcium decreases.[18] The reduced feed intake was observable at ionized calcium below 0.9 mmol/L before the cows had developed other signs of hypocalcemia.[18] Feed intake approached zero when ionized calcium declined to 0.6 mmol/L. This suggests that hypocalcemia may contribute to the reduction in feed intake prepartum and depresses the rumination process ultimately leading to anorexia. Hypercalcemia induced with calcium borogluconate depresses the frequency of rumen contractions but not the amplitude.[19]

In experimental hypocalcemia in sheep, blood flow is reduced by about 60% to all tissues except kidney, heart, lung, and bladder in which the reduction is not as high. During periods of prolonged hypocalcemia in cows and ewes, blood flow to skeletal muscles and the alimentary tract may be reduced to 60–70% of normal for a long period and predispose to the downer cow syndrome. In both cows and sheep there is a significant increase in PO_2 causing an impairment of oxygen uptake by the pulmonary blood flow and an impairment of peripheral tissue uptake of oxygen during hypocalcemia in cows and sheep. Serum calcium and serum phosphate levels are significantly lower in clinical cases than in normal, comparable cows and there is some relationship between the severity of the signs and the degree of biochemical change. The complete response to the parenteral administration of calcium salts in most cases and the occurrence of tetany coincident with hypocalcemia after the IV administration of NaEDTA is further evidence of the importance of hypocalcemia. In addition, some signs indicative of parathyroprivical tetany in other species are observed in the initial stages of milk fever:

- Early excitement
- Muscle twitching
- Tetany, particularly of the hindlimbs
- Hypersensitivity and convulsive movements of the head and limbs.

The IV infusion of EDTA into cows over a period of 4–8 h results in severe hypocalcemia and paresis which is a reliable model for the reproduction of the disease. In the experimental disease, there are additional signs such as excessive salivation, excessive lip and tongue actions and tail lifting. The serum muscle enzyme levels of creatine phosphokinase (CPK) and aminotransferase (AST) increase due to muscle

injury associated with prolonged recumbency. Blood glucose levels increase and serum phosphorus and potassium levels decrease. A prolongation of the ST interval of the electrocardiogram (ECG) occurs, which may be useful as a diagnostic aid if suitable mini-ECG recorders could be made available for field use.

The prolonged infusion of EDTA in sheep over 18 h at a rate to induce hypocalcemia and maintain recumbency resulted in prolonged periods of recumbency ranging from 36 to 64 h before the animals were able to stand. There are also decreases in plasma sodium, plasma potassium, and erythrocyte potassium and prolonged increases in packed cell volumes, which suggests that fluid replacement therapy may be indicated in cattle with prolonged recumbency associated with hypocalcemia. A 4-h IV infusion of EDTA in high erythrocyte potassium and low erythrocyte potassium dairy cows causes decreases in plasma inorganic phosphorus and plasma potassium which are still below normal 24 h later.[20] The AST(SGOT), CPK and packed cell volumes (PCVs) and white blood cell (WBC) counts are also elevated 24 h later. Plasma magnesium and erythrocyte sodium and potassium were decreased but this action was delayed. The increase in PCV was most pronounced in the low erythrocyte potassium cows, which may provide some clues about the pathogenesis of the downer cow syndrome. Some cows may have a more precipitate increase in PCVs due to loss of plasma volume and an inability to mobilize calcium. A 200 mL solution of 10 g of sodium chloride and 0.5 g of potassium chloride can be given IV to sheep safely over a period of 4–8 min to study the effects of administering such hypertonic solutions in downer animals.[20]

29.2.4.5.2

Hypomagnesemia

When hypomagnesemia coexists with hypocalcemia the clinical signs continue but with normal or higher than normal levels, relaxation, muscle weakness, depression, and coma supervene. It is likely that the hypocalcemic tetany is overcome by the relative hypermagnesemia (the ratio of Ca:Mg may change from 6:1 to 2:1) approximating the ratio at which magnesium narcosis develops. There is normally a rise in serum magnesium levels at calving but in those cases of parturient paresis in which tetany is a feature serum magnesium levels are low. These low levels are in many cases expressions of a seasonal hypomagnesemia.

29.2.4.5.3

Hypophosphatemia

Low serum phosphorus levels occur in milk fever and contribute to the clinical signs. Some cases of milk fever may not respond to calcium injectins even though the serum calcium levels return to normal but may appear to recover when the udder is inflated and serum phosphorus levels rise. Field observations indicate sodium acid phosphate given orally or IV may result in recovery of cases not responding initially to calcium salts. However, it is difficult to reconcile the biochemical and clinical findings with low serum phosphorus levels because of the absence of recumbency in other animals with profound hypophosphatemia for long periods. A possible explanation is that the hypophosphatemia which occurs in milk fever is secondary to the hypocalcemia and recumbency rather than being a concurrent event. There is experimental evidence to support this and it also seems probable that the hypophosphatemia could prolong the duration of recumbency.

29.2.4.6

CLINICAL FINDINGS

29.2.4.6.1

Cattle

Three stages of milk fever in cattle are commonly recognized and described.

29.2.4.6.1.1

Stage 1

In the first stage, the cow is still standing. This is also the brief stage of excitement and tetany with hypersensitivity and muscle tremor of the head and limbs. The animal is disinclined to move and does not eat. There may be a slight shaking of the head, protrusion of the tongue, and grinding of the teeth. The rectal temperature is usually normal to slightly above normal. Stiffness of the hindlegs is apparent, the animal is ataxic and falls easily and, on going down, the hindlegs are stuck out stiffly.

Careful observations by owners and veterinarians have revealed an even earlier stage than the first one. It is characterized by anorexia, agalactia, rumen stasis, scant feces and a normal temperature, heart rate and respirations. There are no obvious signs of excitement and hypersensitivity characteristic of the first stage. Affected cows may remain in this prodromal stage for several hours; they are perplexing diagnostically and respond quickly to calcium therapy. Cows with this form of hypocalcemia may be the ‘calcium cyclers' described earlier.

29.2.4.6.1.2

Stage 2

The second stage is prolonged sternal recumbency. Consciousness is usually depressed; the cow has a drowsy appearance in sternal recumbency, usually with a lateral kink in the neck or the head turned into the flank. When approached, some of these cows will open their mouths, extend their head and neck and protrude their tongues, which may be an expression of apprehension and fear in an animal unable to stand. The tetany of the limbs present in the first stage is not present and the cow is unable to stand. The muzzle is dry, the skin and extremities cool, and the rectal temperature subnormal (36–38°C, 97–101°F). There is a marked decrease in the absolute intensity of the heart sounds and an increase in rate (about 80 bpm). The arterial pulse is weak and the venous pressure is also low, making it difficult to raise the jugular veins. The respirations are not markedly affected, although a mild forced expiratory grunt or groan is sometimes audible.

The eyes are usually dry and staring. The pupillary light reflex is incomplete or absent and the diameter of the pupil varies from normal to maximum dilatation. A detailed examination of the pupils of cows with parturient paresis, non-paretic disorders, and non-parturient paresis found that the mean sizes of the pupils were not significantly different from one another.[21] Rather, disparity of the size of the pupils was common. Ruminal stasis and secondary bloat are common and constipation is characteristic. There is also relaxation of the anus and loss of the anal reflex.

In cows which develop hypocalcemia a few hours before or at the time of parturition, the second stage of parturition may be delayed, which is unexpected in a mature cow. Examination of the reproductive tract usually reveals a fully dilated cervix and normal presentation of the fetus. The cow may be in any stage of milk fever and administration of calcium borogluconate IV will usually result in a rapid beneficial response and normal parturition.

Prolapse of the uterus is a common complication of milk fever and often the calcium levels are lower than in parturient cows without uterine prolapse. Thus it is standard practice to treat cases of uterine prolapse with calcium salts IV.

29.2.4.6.1.3

Stage 3

The third stage is lateral recumbency. The cow is almost comatose and although the limbs may be stuck out there is complete flaccidity on passive movement and the cow cannot assume sternal recumbency on its own. In general, the depression of temperature and the cardiovascular system are more marked. The heart sounds are almost inaudible and the rate increased up to 120 bpm; the pulse is almost impalpable and it may be impossible to raise the jugular veins. Bloat is usual because of lateral recumbency. Without treatment, a few animals remain unchanged for several hours but most become progressively worse during a period of several hours and dye quietly from shock in a state of complete collapse.

29.2.4.6.1.3.1

Concurrent hypomagnesemia.

Mild to moderate tetany and hyperesthesia persisting beyond the first stage suggests a concurrent hypomagnesemia. There is excitement and fibrillary twitching of the eyelids and tetanic convulsions are readily precipitated by sound or touch. Trismus may be present. The heart and respiratory rates are increased and the heart sounds are much louder than normal. Without treatment death occurs during a convulsion.

29.2.4.6.1.3.2

Concurrent hypophosphatemia.

With a concurrent hypophosphatemia, the clinical findings are typical of milk fever which responds to calcium therapy in all respects except that the cow is unable to stand after treatment.

29.2.4.6.2

Sheep and goats

The disease in pastured ewes is similar to that in cattle. The early signs include a stilty, proppy gait and tremor of the shoulder muscles. Recumbency follows, sometimes with tetany of the limbs but the proportion of ewes with hypocalcemia which are recumbent in the early stages is much less than in cattle. A similar generalization applies to female goats. The characteristic posture is sternal recumbency, with the legs under the body or stretched out behind. The head is rested on the ground, there may be an accumulation of mucus exudate in the nostrils. The venous blood pressure is low and the pulse impalpable. Mental depression is evidenced by a drowsy appearance and depression of the corneal reflex. There is loss of anal reflex, constipation, tachycardia, hyposensitivity,

ruminal stasis and tympany, salivation and tachypnea.[22] Response to parenteral treatment with calcium salts is rapid, the ewe is normal 30 min after a SC injection. Death often occurs within 6–12 h if treatment is not administered. The syndrome is usually more severe in pregnant than in lactating ewes, possibly because of the simultaneous occurrence of pregnancy toxemia or hypomagnesemia. Fat late pregnant ewes on high grain diets indoors or in feedlots show a similar syndrome accompanied by prolapses of the vagina and intestine.

29.2.4.6.3

Pigs

As in cattle, signs develop within a few hours of farrowing. There is restlessness, a normal temperature and anorexia followed by inability to rise and later lateral recumbency and coma. Milk flow is decreased.

29.2.4.7

CLINICAL PATHOLOGY

Total serum calcium levels are reduced to below 8 mg/dL (2.0 mmol/L), usually to below 5 mg (1.2 mmol/L) and sometimes to as low as 2 mg (0.5 mmol/L). The reduction is usually, but not always, proportional to the severity of the clinical syndrome. Average figures for total serum calcium levels in the three species are cows 5.2± 1.2 mg/dL (1.30± 0.30 mmol/L), ewes 4.6± 1.5 mg/dL (1.15± 0.37 mmol/L), goat does 3.8± 0.6 mg/dL (0.94± 0.15 mmol/L).

Total serum calcium levels are a basis for comparison between species. Blood levels of ionized calcium are a better indicator of calcium status but their estimation has been too difficult until recently. Although total serum calcium levels are used to express the animals' status with regard to calcium, it is possible that differences between the ionized and non-ionized compartments of total calcium may be more important than the total level. The development of a reliable calcium ion-selective electrode now makes it possible quickly and directly to determine the biologically active portion of calcium in plasma or serum. However, the correlation between ionized and total calcium is excellent. Equine, bovine, and ovine blood may be stored for up to 48 h without any clinically relevant alteration of blood calcium ion concentration.

Normal levels of **ionized calcium** (as CaF) in venous whole blood of cows are 4.3–5.1 mg/dL (1.06–1.26 mmol/L) serum, slight hypocalcemia 4.2–3.2 mg/dL (1.05–0.80 mmol/L), moderate 3.2–2.0 mg/dL (0.79–0.50 mmol/L) and severe hypocalcemia <2.0 mg/dL (<0.50 1632 1633

mmol/L) serum. Total serum calcium levels are reduced below normal in all cows at calving whether they have milk fever or not, but not in ewes.

A commercially available water hardness test kit can be used as a rapid, inexpensive method of estimating serum calcium concentrations for the diagnosis of hypocalcemia in dairy cattle.[23] There is a high correlation and linear relationship between the test kit results and a standard laboratory based method. However, the blood sample must be centrifuged to obtain serum for use in the test kit.

Serum **magnesium** levels are usually moderately elevated to 4–5 mg/dL (1.65–2.06 mmol/L) but in some areas low levels may be encountered, especially in cows at pasture.

Serum **inorganic phosphorus** levels are usually depressed to 1.5–3.0 mg/dL (0.48–0.97 mmol/L).

Blood glucose levels are usually normal, although they may be depressed if ketosis occurs concurrently. Higher than normal blood glucose levels are likely to occur in cases of long duration and are therefore an indication of a poorer than normal prognosis.

Table 29.5 Differential diagnosis of common causes of recumbency in parturient adult cattle

Disease	Epidemiology	Clinical signs	Clinical pathology	Response to treatment
Milk fever (parturient paresis)	Mature cows, within 48 h of calving, some in mid-lactation	Early excitement and tetany. Then depression, coma, hypothermia, flaccidity, pupil dilatation, weak heart sounds. No rumen movements. HR increases as state worsens	Hypocalcemia, <5 mg/dL (1.25 mmol/L) calcium. High serum magnesium, >3 mg/dL (1.25 mmol/L) low inorganic phosphate, <3 mg/dL (0.9 mmol/L)	Rapid, characteristic response (muscle tremor, sweating on muzzle, defecation, urination, pulse amplitude and heart sound intensity improves first) after IV injection soluble calcium salt
Downer cows following milk fever	Most common in situation where milk fever and lactation tetany are common and intensity of treatment is lax; cows are left down too long before treatment	Moderately bright, active, eating. Temp. slightly raised, HR 80–100. Unable to stand but tries – 'creepers'. When dull and depressed, are 'non-alert downers'. Long course 1–2 weeks	Variable. May be low inorganic phosphate, or potassium, or glucose Ketonuria, usually proteinuria CPK and SGOT elevated	Variable response to calcium, phosphorus and potassium salts. Fluid therapy and provision of deep bedding and hourly rolling from side to side are necessary

Carbohydrate engorgement	Access to large amount readily fermentable carbohydrate when not accustomed. Enzootic in high grain rations in feedlots. Intensive IV fluid and electrolyte therapy necessary for survival	Severe gastrointestinal atony with complete cessation of ruminal activity. Fluid splashing sounds in rumen Severe dehydration, circulatory failure. Apparent blindness, then recumbency and too weak to rise. Soft odoriferous feces	Hemoconcentration with severe acidosis, pH of rumen juice below 5, serum phosphorus levels up to 3–5 mmol/L, serum calcium levels depressed. No living protozoa in rumen	Rumenotomy or rumen lavage may be necessary. Alkalinizing agents
Hypomagnesemia (lactation, grass tetany)	All classes of cattle, but most recently calved cows Age no barrier and cases occur up to several months after calving. May occur in pregnant beef cattle	Excitement, hypersensitivity, muscle tremor, tetany. Recumbent with tetanic convulsions, loud heart sounds, rapid rate. Subacute cases remain standing	Low serum magnesium, <1.2 mg/dL (0.5 mmol/L)	Even after IV injection response in a severe case may take 30 min, much slower than response to calcium in milk fever
Severe toxemia (acute diffuse peritonitis, coliform mastitis)	Sporadic only. Mastitis most common where hygiene poor. Peritonitis due to foreign body perforation of reticulum, rupture of uterus or vagina	Recumbency, depression to coma, sleepy, dry nose, hypothermia, gut stasis, *HR over 100/min*, may be grunting. Examine mammary gland. Examine abdomen for abdominal disease	Profound leukopenia. Serum calcium may be as low as 7–8 mg/dL (1.75–2.0 mmol/L). Examine milk (CMT)	Require supportive response for toxemia and shock. Response is poor and temporary. Prognosis very bad. May die if treated IV with calcium or magnesium salts.

Fat cow syndrome	Fat dairy or beef cows in late gestation or at parturition. Some predisposing cause precipitates illness in fat animals	Excessive body condition, anorexia, apathy, depression, recumbency and looks like milk fever, scant soft feces, ketonuria	Evidence of hepatic disease.	Will recover if begin to eat. Treat with fluids, glucose, insulin. Provide good quality palatable roughage
Physical injuries	Ruptured gastrocnemius, dislocation of hip, etc. Sporadic sequelae to milk fever, may be contributed to by osteoporosis, slippery ground surface, stimulating to rise too early	As for MOP with ruptured gastrocnemius, hock remains on ground when standing. Excessive lateral mobility of limb with hip dislocation	Increase CPK and SGOT	Supportive therapy, deep bedding, and frequent rolling.
Acute hypokalemia	Dairy cattle treated for ketosis with isoflupredone acetate. Calved within previous 30 days	Recumbent, very weak, appear flaccid, in sternal or lateral recumbency, unable to support head off ground, hold head in flank, anorexia; cardiac arrhythmia may present. Most die or are euthanaized	Serum potassium below 2.3 mEq/L. Muscle necrosis at necropsy	Potassium chloride IV or orally

Bovine spongiform encephalopathy	Mostly in dairy cattle. Eating concentrate made from animals with BSE. Long incubation period.	Insidious onset, clinical course several weeks, changes in behavior, hyperesthesia, ataxia, loss of weight, kick during milking, knuckling, progressive weakness leading to recumbency	Laboratory examination of brain for presence of prions	Nil

29.2.4.7.1

Serum muscle enzymes

Prolonged recumbency results in ischemic muscle necrosis and increases in the serum muscle enzymes creatine phosphokinase (CPK) and aspartate aminotransferase (AST) or SGOT. During prolonged recumbency following treatment for milk fever, the levels of CPK will remain elevated if muscle necrosis is progressive in animals which are not rolled from side to side every few hours to reduce the effects of compression on the large muscle groups of the pelvic limbs (see Downer cow syndrome).

29.2.4.7.2

Hemogram

Changes in the leukocyte count include an eosinopenia, a neutrophilia, and a lymphopenia suggestive of adrenal cortical hyperactivity, but similar changes occur at calving in cows which do not develop parturient paresis. High plasma cortisol levels and packed cell volumes occur in cows with milk fever and are higher still in cows that do not respond to treatment. They are expressions of stress and dehydration. Clinicopathological findings in the other species are not described in detail except with regard to depression of total serum calcium levels.

29.2.4.8

NECROPSY FINDINGS

There are no gross or histological changes unless concurrent disease is present.

29.2.4.9

DIFFERENTIAL DIAGNOSIS

A diagnosis of milk fever is based on the occurrence of paresis and depression of consciousness in animals following parturition. The diagnosis is supported by a favorable

response to treatment with parenteral injections of calcium solutions and by biochemical examination of the blood. In ewes, the history usually contains some reference to recent physical stress and the disease is more common in the period preceding lambing.

In the immediate postpartum period, there are several diseases which cause recumbency in cows and their differentiation is summarized in Table 29.5.

1633

1634

Several diseases which occur at the time of parturition must be differentiated from milk fever in cattle. These are grouped here according to:

- Other metabolic diseases
- Diseases associated with toxemia and shock
- Injuries to the pelvis and pelvic limbs
- Degenerative myopathy
- Downer cow syndrome.

29.2.4.9.1

Metabolic diseases

Hypomagnesemia may occur as the sole cause of recumbency or it may accompany a primary hypocalcemia so that the case presented is one of parturient paresis complicated by lactation tetany. Hyperesthesia, tetany, tachycardia, and convulsions are common instead of the typical findings of depression and paresis in milk fever.

Hypophosphatemia, which commonly accompanies milk fever, is suggested as a cause of continued recumbency in cows after partial response to calcium therapy; serum inorganic phosphorus levels are low and return to normal if the cow stands or following treatment with phosphate salts. A sudden onset of recumbency in dairy cows associated with a marginal deficiency of phosphorus has been reported.[24]

Hypokalemia in dairy cows is characterized by extreme weakness or recumbency, especially after treatment for ketosis with isoflupredone. Hypokalemia is marked as ranging from 1.4 to 2.3 mEq/L. The case-fatality rate is high in spite of therapy with potassium. Hypokalemic myopathy is present at necropsy.

Ketosis may complicate milk fever, in which case the animal responds to calcium therapy by standing but continues to manifest the clinical signs of ketosis, including in some cases the nervous signs of licking, circling, and abnormal voice.

29.2.4.9.2

Diseases associated with toxemia and shock

During the immediate postparturient period, several diseases occur commonly and are characterized by toxemia.

Peracute coliform mastitis is characterized by:

- Fever initially followed by hypothermia
- Tachycardia
- Dehydration
- Weakness and recumbency

1634

1635

- Depression
- Ruminal stasis
- Diarrhea in some
- Enlarged mammary gland(s) with watery and serous-like secretions with small particles barely visible.

Aspiration pneumonia secondary to regurgitation and aspiration of rumen contents may occur as a complication of thirdstage milk fever. Fever, dyspnea, expiratory grunt, severe depression and anxiety are common. Auscultation of the lungs reveals the presence of abnormal lung sounds. Aspiration pneumonia should be suspected if the animal has been lying on its side, especially if there is evidence of regurgitation of ruminal contents from the nostrils, no matter how small the amount, or if there is a history of the animal having been drenched. Abnormal auscultatory findings may not be detectable until the second day. Early diagnosis is imperative if the animal is to be saved and the mortality rate is always high.

Acute diffuse peritonitis resulting from traumatic perforation of the reticulum or uterus is characterized by:

- Severe depression
- Fever

- Weakness and recumbency
- Ruminal stasis
- Dehydration
- Grunting or groaning with each respiration
- Tachycardia
- Fluid splashing sounds on ballottement of the abdomen (paralytic ileus).

Carbohydrate engorgement results in:

- Depression
- Weakness
- Sternal recumbency
- Dehydration
- Tachycardia
- Ruminal stasis and moderate bloat
- Fluid-splashing sounds over rumen
- Low rumen juice pH
- Diarrhea
- Hypothermia
- Cool extremities
- Progressive worsening if not treated.

Many cases resemble second-stage milk fever.

Toxemic septic metritis occurs most commonly within a few days after parturition and is characterized by:

- Depression

- Anorexia
- Fever
- Tachycardia (100–120 bpm)
- Ruminal stasis
- Presence of foul-smelling uterine discharge found on vaginal examination.

The fetal placenta may be retained. Some affected cows are weak and prefer recumbency, which resembles milk fever. Prolapse and rupture of uterus causes varying degrees of:

- Shock with tachycardia
- Hypothermia and cool extremities
- Weakness and recumbency
- Rapid death.

A history of difficult parturition or assisted dystocia with fetotomy may be associated with rupture of the uterus. The administration of calcium salts may cause ventricular fibrillation and sudden death.

Although some elevation of the temperature may be observed in these severe toxemic states, it is more usual to find a subnormal temperature. The response to calcium therapy is usually a marked increase in heart rate and death during the injection is common. Every case of recumbency must be carefully examined as these conditions may occur either independently or as complications of parturient paresis. In our experience, about 25% of cases of postparturient recumbency in cows are due primarily to toxemia or injury rather than to hypocalcemia.

29.2.4.9.3

Injuries to the pelvis and pelvic limbs

Injuries to the pelvis and pelvic limbs are common at parturition because of the marked relaxation of the ligaments of the pelvic girdle. Seven types of leg abnormality have been described in this group at an incidence level of 8.5% in 400 consecutive cases of parturient paresis. The abnormalities included radial paralysis, dislocation of the hips and rupture of gastrocnemius muscle. In most instances the affected animals are down and

unable to stand but they eat, drink, urinate and defecate normally, have a normal temperature and heart rate and make strong efforts to stand, particularly with the forelimbs.

Maternal obstetrical paralysis is the most common injury. Although this occurs most frequently in heifers after a difficult parturition, it may also occur in adult animals following an easy birth and occasionally before parturition, especially in cows in poor body condition. The mildest form is evidenced by a frequent kicking movement of a hindleg, as though something was stuck between the claws. All degrees of severity from this, through knuckling and weakness of one or both hindlegs, to complete inability to rise may occur, but sensation in the affected limb is usually normal. There is traumatic injury to the pelvic nerves during passage of the calf. There are often gross hemorrhages, both deep and superficial and histopathological degeneration of the sciatic nerves. In individual animals, injury to the obturator nerves is common and results in defective adduction of the hindlimbs. The position of the hindlimbs may be normal but in severe cases, especially those with extensive hematoma along the sciatic nerve trunk, the leg may be held extended with the toe reaching the elbow as in dislocation of the hip; however in the latter case there is exaggerated lateral mobility of the limb. Additional injuries causing recumbency near parturition include those associated with degenerative myopathy, dislocation of the hip and ventral hernia.

Dislocation of the coxofemoral joint can cause recumbency and inability to stand in some cows, while others can stand and move around. Recumbent cows are usually in sternal recumbency and the affected limb is abducted excessively. In standing cows, the affected limb is usually extended, often difficult to flex and often rotated about its long axis. The diagnostic criteria are:

- Sudden onset of lameness with the affected limb extended and possibly rotated
- Displacement of the greater trochanter of the femur from its normal position relative to the ischiatic tuber and coxal tuber of the pelvis
- Ability to abduct the limb manually beyond its normal range
- Crepitus in the hip on abduction and rotation of the limb
- Ability to palpate the femoral head per rectum or per vaginum against the cranial border of the ilium or pubis in cases of cranioventral dislocation, or in the obturator foramen in cases of caudoventral dislocation.

Manual replacement by closed reduction is successful in 80% of craniodorsal dislocation and 65% in caudodorsal dislocation. The ability to stand before reduction is the most useful prognostic aid.

29.2.4.9.4

Degenerative myopathy (ischemic muscle necrosis)

Degenerative myopathy affecting primarily the large muscles of the thighs, occurs commonly in cattle which have been recumbent for more than several hours. At necropsy, large masses of pale muscle are present surrounded by muscle of normal color. Clinically it is indistinguishable from sciatic nerve paralysis. Markedly increased serum levels of CPK occur in cows recumbent for several hours following the initial episode of milk fever due to ischemic necrosis. Persistent elevation of CPK indicates progressive ischemic muscle necrosis due to continued compression of large muscle masses of the pelvic limbs. Rupture of the gastrocnemius muscle or separation of its tendon from either the muscle or the tuber calcis may also cause myopathy.

29.2.4.9.5

Downer cow syndrome

Downer cow syndrome is a common sequel to milk fever in which the cow was in sternal recumbency for several hours before being treated with calcium. Following treatment, most of the clinical findings associated with milk fever resolved except the animal was unable to stand. Clinically, the animal may be normal except for recumbency and will commonly recover and stand normally within several hours or a few days. Most downer cows eat and drink normally, their vital signs are within the normal range and their alimentary tract function is normal. However, some are anorexic, may not drink, exhibit bizarre movements of lying in lateral recumbency, and dorsally extend their head and neck frequently, moan and groan frequently, assume a frog-legged posture with their pelvic limbs and crawl or creep around the stall and may die or are euthanized for humane reasons in a few days. The diagnostic dilemma with these cows is that they resemble milk fever and whether or not to treat them with additional amounts of calcium salts is questionable.

29.2.4.9.6

Non-parturient hypocalcemia

Paresis with mental depression and associated with low total serum calcium levels can occur in cows at times other than at parturition. The cause is largely unexplained but the syndrome occurs rarely in animals other than ruminants. Hypocalcemia may occur after

gorging on grain and may be a significant factor in particular cases. Sudden rumen stasis due to traumatic reticulitis may rarely cause hypocalcemic paresis. Diarrhea, particularly when cattle or sheep are placed on new lush pasture, may also precipitate an attack. Access to plants rich in oxalates may have a similar effect, particularly if the animals are unaccustomed to the plants. Affected animals respond well to calcium therapy but relapse is likely unless the primary cause is corrected. The differential diagnosis of diseases of non-parturient cows manifested principally by recumbency is also summarized in Table 29.5.

1635

1636

29.2.4.9.7

Hypocalcemic paresis in sheep and goats

Hypocalcemia in sheep must be differentiated from pregnancy toxemia in which the course is much longer, the signs indicate cerebral involvement and the disease is restricted to pregnant ewes. There is no response to calcium therapy and a positive test for ketonuria is almost diagnostic of the disease. At parturition, goats are susceptible to enterotoxemia and hypoglycemia (rarely), both of which present clinical signs similar to parturient paresis.

29.2.4.9.8

Hypocalcemia in sows

Hypocalcemia is rare in sows. The disease must be differentiated from the mastitis, metritis and agalactia complex, which is characterized by:

- Fever
- Agalactia
- Anorexia
- Toxemia
- Enlarged mammary glands.

29.2.4.9.9

Treatment

Every effort should be made to treat affected cows as soon as possible after clinical signs are obvious. Treatment during the first stage of the disease, before the cow is recumbent, is the ideal situation. The longer the interval between the time the cow first becomes recumbent and treatment, the greater the incidence of the downer cow syndrome due to ischemic muscle necrosis from prolonged recumbency. Complications of milk fever

occur when cows have been in sternal recumbency for more than 4 h. Farmers must be educated to appreciate the importance of early treatment. Cows found in lateral recumbency (third stage) should be placed in sternal recumbency until treatment is available. This will reduce the chances of aspiration if the cow regurgitates. Cows that have difficulty finding solid, non-slip footing beneath them, for example, a slippery barn floor or slippery mud, will often not try to stand and may develop ischemic myonecrosis. Avoidance of this complication necessitates the placement of rubber or other mats under the cow or transportation of the cow to a piece of pasture with a dense sward on it. A temperature of greater than 39°C (102°F) is an indication of a higher than average mortality rate due to pre-existing complications.

29.2.4.9.10

Standard treatment

Calcium borogluconate at 10–200 g is the treatment of choice. The solutions available vary from 18 to 40% calcium borogluconate. Most cows with milk fever can be treated successfully with 8–10 g of calcium (calcium borogluconate is 8.3% calcium). For cattle, 400–800 mL of a 25% solution is the usual dose. The dose rate of calcium is frequently under discussion. There is a general tendency for veterinarians to underdose with calcium salts, largely because of toxic effects which tend to occur when all of the calcium is given IV. As an initial dose a large cow (540–590 kg) requires 800–1000 mL of a 25% solution and a small cow (320–360 kg) 400–500 mL. Underdosing increases the chances of incomplete response, with inability of the cow to rise, or of relapse. In general, 12 g of calcium is superior to 8 g, which in turn is superior to 6 g.

The standard rate of administration is a rapid intravenous administration of the calculated dose of calcium borogluconate (often supplemented with phosphorus, magnesium, and glucose) over a period of 15 min. Hypercalcemia (up to 22 mg/dL) occurs following IV administration of calcium borogluconate over a period of 12–15 min. The plasma calcium concentration will gradually decline over a period of several hours by which time calcium homeostasis should begin to occur and levels return to normal by 12–24 h following treatment. However, in some cows calcium homeostasis is ineffective and subclinical or clinical hypocalcemia may recur.

Because up to 50% of cows may not respond to the initial rapid administration, it has been postulated that the increases in electrolytes are only transient and that slower IV infusion would be more effective.[25] The slow infusion of a calcium solution via an IV indwelling catheter over 6 h was compared with the conventional single IV

administration of 600 mL of a 40% calcium borogluconate solution containing 18.78 g calcium gluconate and borogluconate with 6% magnesium hypophosphite (11.82 g magnesium hypophosphite) over 15 min in cows recumbent with milk fever.[25] Cows receiving the rapid infusion responded more quickly and stood sooner and their demeanor returned to normal more quickly. The slow infusion consisted of 200 mL IV over a 10 min period and the remaining 400 mL added to 10 L of a solution of 90 g sodium chloride and 500 g glucose and given via IV drip over a 6 h period at a rate of 1.7 L/h. In cows treated rapidly, the serum calcium and magnesium levels increased rapidly compared with the infused cows.[26] In both groups, the serum inorganic phosphorus increased slowly with the mean concentration reaching a maximum at 3 h and then decreasing slightly. Some cows are still hypophosphatemic several hours later.

In sheep and goats, the recommended amount is 15–20 g IV with an optional 5–10 g SC. Sows should receive 100–150 mL of a similar solution IV or SC.

29.2.4.9.11

Routes of administration

29.2.4.9.11.1

IV and SC routes

The intravenous (IV) route is preferred because the response is rapid and obvious. The heart should be auscultated throughout the intravenous administration for evidence of gross arrhythmia, bradycardia, and tachycardia. If any of these occurs, the intravenous administration should be interrupted and continued only after the heart sounds return to normal. If the cardiac irregularity continues, the remainder of the solution can be given subcutaneously. The best recommendation is to give as much of the solution as possible intravenously and the remainder subcutaneously. The common practice of giving half the dose intravenously and half subcutaneously is a reasonable compromise because with this method there are fewer relapses. If a cow has been previously treated subcutaneously by the farmer, additional calcium given intravenously may cause toxicity if the improved circulation enhances the absorption of the subcutaneous calcium.

29.2.4.9.11.2

SC route

The subcutaneous (SC) route is commonly used by farmers who treat affected cows at the first sign of hypocalcemia, preferably during the first stage when the cow is still standing or as prophylaxis to all high-risk cows immediately after calving. The SC

route has also been used by veterinarians when the effects of IV administration of calcium are uncertain or if an unusual response occurs during IV administration. There are limitations to the effectiveness of SC calcium solutions given to cows with milk fever.[27] Cows given 300 mL of 33.3% or 40% calcium borogluconate SC had serum calcium levels of 1.4 mmol/L; those receiving 600 mL had serum calcium levels of 2.1 mmol/L, at mean intervals of 4.8 and 12.0 h between treatments by the herdsman and veterinary attention.[27] At the time of sampling, 48% of cows receiving 600 mL of calcium borogluconate had a serum calcium level below 2.0 mmol/L. If the veterinarian is unable to treat the cow within 1 h, a dose of 600 mL of 40% calcium borogluconate should be given SC in two sites and massaged well to promote absorption. Waiting for more than 1 h to assess the effect of one treatment SC is regarded as conducive to development of the downer cow syndrome. The cow should then be placed in a dry area with her limbs positioned to minimize ischemic necrosis and covered with straw and tarpaulins until the veterinarian arrives.

Toxemic cows are very susceptible to the IV administration of calcium borogluconate and death may occur. In such cases the heart rate increases markedly (up to 160 bpm), there is respiratory distress, trembling and collapse and the cow dies within a few minutes. SC or IP administration is preferred in cows with severe toxemia due to aspiration pneumonia, metritis, and mastitis. 1636 1637

29.2.4.9.11.3

Oral route

A further aid to parenteral therapy with solutions of calcium salts, especially for the purpose of increasing recovery rates and preventing relapses, is the oral administration of gels containing calcium chloride, which are described under prevention.

29.2.4.9.12

Typical response to calcium borogluconate

Cows with milk fever exhibit a typical pattern of response to calcium borogluconate IV if the response is favorable, including:

- Belching
- Muscle tremor, particularly of the flanks and often extending to the whole body
- Slowing and improvement in the amplitude and pressures of the pulse
- Increase in the intensity of the heart sounds

- Sweating of the muzzle
- Defecation.

The feces are in the form of a firm fecal ball with a firm crust and covered with mucus, occasionally with a few flecks of blood. Urination usually does not follow until the cow stands. A slight transitory tetany of the limbs may also be observed. Many cows will eat and drink within minutes following successful treatment if offered feed and water.

The rate of response to treatment is affected by many factors as set out below and it is unwise to quote what might be expected as an acceptable rate of recovery after treatment. This is particularly true if cows are treated by the farmer and only difficult cases are presented to the veterinarian. In general, if all cases are considered and there are no exceptional circumstances, recovery can be expected immediately after treatment in about 60% of cases and in a further 15% after 2 h; 10% have recoveries complicated by one of the diseases discussed earlier and 15% can be expected either to die or to require disposal. Of those which recover after one treatment, 25–30% can be expected to relapse and require further treatment.

29.2.4.9.13

Unfavorable response to calcium borogluconate

An unfavorable response is characterized by a marked increase in heart rate in cows affected with toxemia and acute heart block in apparently normal animals especially with overdosage, with too rapid injection and in cases in which treatment has been unduly prolonged. In the latter, the maximum tolerated dose of calcium borogluconate by IV administration is about 250 mL of a 25% solution. Overdosage may occur when farmers treat cases unsuccessfully by multiple SC injections and these are followed by an IV dose. When the peripheral circulation is poor, it is probable that the calcium administered SC is not absorbed until the circulation improves following the IV injection and the large doses of calcium then absorbed cause acute toxicity. In all cases of IV injection, the circulation must be monitored closely. Some degree of arrhythmia occurs in most cases but if there is gross arrhythmia or a sudden increase in heart rate, the injection should be stopped temporarily or continued with great caution. In normal circumstances at least 10 min should be taken to administer the standard dose. The acute toxic effect of calcium salts seems to be exerted specifically on heart muscle with a great variety of defects occurring in cardiac action; the defect type depends on the specific calcium salt used and the speed of injection. ECG changes after induced hypercalcemia

show increased ventricular activity and reduced atrial activity. Atropine is capable of abolishing the resulting arrhythmia.

Sudden death may also occur after calcium injections if the cow is excited or frightened, which may be due to an increased sensitivity to epinephrine. When affected cows are exposed to the sun or a hot, humid atmosphere, heatstroke may be a complicating factor. In such cases an attempt should be made to reduce the temperature to below 39.5°C (103°F) before the calcium is administered. The incidence of cardiac arrhythmia and other abnormalities as detected by ECG during treatment with calcium salts IV is so high that there are doubts expressed about the suitability of this form of treatment.

Chronic toxicity may also occur. In laboratory animals, severe uremia due to extensive calcium deposits in the kidney occur after the SC injection of calcium chloride and borogluconate and similar deposits are often seen at necropsy in cows dying after multiple injections of calcium salts administered at short intervals.

29.2.4.9.14

Failure to respond to treatment

A failure to respond favorably to treatment may be due to an incorrect or incomplete diagnosis, or inadequate treatment. A poor response to treatment includes: (1) no observable changes in the clinical findings immediately following the calcium administration or (2) the animal may respond to the calcium in all respects with the exception of being unable to stand for varying periods of time following treatment. An inadequate response also includes relapses after successful recovery, which usually occur within 48 h of the previous treatment. Relapses are more common in certain individual cows such as mature Jersey cows, which may experience as many as five or six episodes around one calving. Also, the incidence of relapse is much higher in cases which occur just before calving than in those which occur afterwards. The needs of individual animals for calcium replacement vary widely, depending on their body weight and the degree of hypocalcemia. Incomplete responses may be more common in older cows and may be associated with diminished skeletal reserves of calcium and inability of the normal mechanisms to maintain serum calcium levels during the period of excessive demands of lactation. The duration of the illness and the posture of the cow also affect the response. In an extensive field study, there were no downer cows or deaths in cows still standing when first treated, 13% of downers and 2% of deaths occurred in cows in sternal recumbency and 37% of downers and 12% of deaths occurred in cows in lateral recumbency when first treated.[28] Therefore, in general, the longer the period from onset

of milk fever to treatment, the longer the period of post-treatment recumbency and the higher the case-fatality rate. In another study, 67% of cows recovered after a single treatment, 90% after two treatments, and 92–99% after three treatments. After routine treatment, 37% of cases rose unassisted within 10 min, 23% required some assistance, 26% recovered after longer periods of recumbency, and 14% died or were destroyed or sold for slaughter. The best procedure to follow if response does not occur is to revisit the animal at 12-hourly intervals and check the diagnosis. If no other cause of the recumbency can be determined, the initial treatment can be repeated on a maximum of three occasions. Beyond this point, further calcium therapy is seldom effective. A low body temperature, due probably to exposure to low environmental temperature and increased wind velocities, is positively correlated with a high proportion of deaths and poor responses.

At the second visit, solutions containing either phosphorus, magnesium, or dextrose may be administered, depending upon the clinical signs presented and the results of available biochemical tests. Glucose is usually administered as 500 mL of a 40% solution, sodium acid phosphate as 200 mL of a 15% solution, and magnesium sulfate as 200–400 mL of a 15% solution. Composite solutions containing calcium, magnesium, phosphorus and glucose are also in common use as initial treatments. There is controversy about these socalled ‘polypharmacy' preparations. They have no advantage, but are likely to remain popular when milk fever cases are complicated by metabolic disorders other than hypocalcemia. They have no effect on the relapse rate when compared with calcium salts alone. 1637 1638

29.2.4.9.15

Udder insufflation

Insufflation of the udder with air was an alternative treatment for cows which continued to relapse following repeated calcium injections. With the availability and effectiveness of orally administered calcium gels, udder insufflation cannot be recommended.

29.2.4.10

GENERAL MANAGEMENT AND CLINICAL CARE PROCEDURES

The care of the cow and the calf following milk fever is important. The calf should be removed from the cow and for the first 48 h only sufficient milk should be drawn for the calf's maintenance. A gradual return to full milking can then be permitted. If the cow is recumbent for any length of time, she must be kept propped up in sternal recumbency and not left in lateral recumbency, which may result in regurgitation and aspiration pneumonia.

The cow should be rolled from side to side every few hours and provided with adequate bedding or moved to a suitable non-slip ground surface. In extreme climatic conditions, erection of a shelter over the cow is advisable if she cannot be moved to permanent shelter. If a cow is recumbent for more than 48 h, assisted lifting using appropriate cow lifters several times daily should be considered. However, heroic measures to get cows to stand should be avoided. Gentle nudging in the ribs or the use of an electric prod are the maximum stimulants advised. The best assistance that can be given to a cow attempting to stand is a good heave at the base of the tail when she is halfway up.

29.2.4.11

CONTROL

Various methods for the control of milk fever in ruminants, especially dairy cows, are available. They include dietary management during the transition period before and after calving, administration of calcium gels orally at the time of parturition and administration of vitamin D and its metabolites and analogs immediately before parturition to enhance the mobilization of calcium. When the incidence of milk fever increases to above 10% of high-risk cows (third or later lactations), a specific control program is necessary. When the incidence is low, a specific control program may not be economical and the alternative is to monitor cows carefully at the time of parturition and for 48 h after parturition and treat affected animals during the first stage of the disease if possible.

Various aspects of the literature on the principles of control of milk fever in cattle, under different circumstances have been reviewed.[29–31] The different strategies for the control of milk fever in dairy cows has been examined by expert opinions.[32] The two control strategies predicted to be most relevant were calcium gel orally peripartum used alone and in combination with a low-calcium diet. Several control strategies for milk fever in dairy herds have been evaluated by stochastic simulation in order to analyze the technical and economic effects at the herd level and to assess frameworks for decision support system development.[33] The simulated technical and economic effects indicated a complex interaction between herd and control strategy. In general, the most comprehensive control strategies were economically inferior to similar but less comprehensive control strategies.

29.2.4.11.1

Dietary management during prepartum period

For purposes of optimal nutritional management of dairy cows which are fed prepared feeds (not pasture-based), the dry period is divided into at least two distinct categories – cows in the early and middle portion of the dry period (*far-off* or *regular* dry cow group)

and cows in the final 3 weeks prior to their calving date (*pre-fresh, transition, close-up, near, lead feeding,* or *steam-up* group).[31] Large herds may have additional subgroups of dry cows depending on management circumstances and facilities available. Special attention must be given to the mineral nutrition of the close-up group. Minerals should be provided to close-up cows in known quantities, either as part of a grain mixture or total mixed ration (TMR).

29.2.4.11.1.1

Calcium and phosphorus nutrition

29.2.4.11.1.1.1

Level of calcium in diet

Diets high in calcium during the prepartum period can result in a high incidence of milk fever and diets low in calcium will reduce the incidence of milk fever in dairy cows. Feeding more than 100 g of calcium daily during the dry period is associated with an increased incidence of milk fever. A cow weighing 500 kg requires only about 33 g/daily of calcium to meet maintenance and fetal calcium demands in the last 2 months of late gestation.[30] Low calcium diets (20 g Ca/d) fed during the last 2 weeks before parturition are highly reliable and effective. The low levels of dietary calcium activate the calcium homeostatic mechanisms before calving and the cow is more able to absorb calcium from the digestive tract and to mobilize calcium from bone reserves. At least 14 days of a low calcium diet are required to be effective in minimizing the incidence of milk fever. Feeding dry cows rations low in calcium results in activation of the calcium homeostatic mechanisms before calving making the cow able to mobilize the large quantities of calcium for the final stages of prenatal growth and colostrum production. When dietary calcium availability is decreased below calcium requirements, the cow is brought into negative calcium balance. This leads to a secretion of parathyroid (PTH) which increases renal reabsorption of calcium within minutes, stimulates calcium resorption from bone within hours to days, and stimulates renal vitamin D metabolism to towards production of 1,25-dihydroxyvitamin D (1,25-$(OH)_2$D) within hours or days. The (1,25-$(OH)_2$D) stimulates the active transport of calcium across the intestinal epithelial cells. During bone resorption, urinary excretion of pyridinoline and deoxypyridinoline, derived from collagen breakdown, is increased.

29.2.4.11.1.1.2

Practicality of feeding diets low in calcium

There are practical problems with the implementation of the recommendation to feed diets low in calcium. It is difficult to reduce the amounts of calcium and phosphorus fed to cows for several reasons:

- Inability to grow sufficient quantities of feeds, such as corn silage, for the entire herd
- Suitability of land for legume crops which are high in calcium
- Inability to add sufficient phosphorus to lower the ratio of calcium to phosphorus to palatability when quantities of phosphorus are added to the ration.

Most farms utilizing home-grown forages, especially alfalfa, find it difficult to obtain forages which are low in calcium. A low calcium diet can be achieved by replacing some or all alfalfa hay in the dry cow diet with grass hay and using additional corn silage and concentrates. While feeding diets low in calcium during the prepartum period is very effective, the very low calcium intake required necessitates that the cow be in negative calcium balance and in a state of withdrawal of calcium from bone.

29.2.4.11.1.1.3

Binding dietary calcium

It is possible to prevent milk fever and subclinical hypocalcemia by adding a substance to the feed capable of binding dietary calcium and making it unavailable for absorption. The oral administration of sodium aluminum silicate or zinc oxide to cows in late lactation results in a decrease in total serum calcium.[34] Supplementing the dry cow ration with sodium aluminium silicate (zeolite A) at the rate of 1.4 kg of zeolite pellets per day (0.7 kg of pure zeolite) for the last 2 weeks of pregnancy results in an increase in plasma calcium around calving.[35] Plasma magnesium and inorganic phosphate levels were decreased and serum 1,25-$(OH)_2D$ was significantly increased.[35] Feed intake was decreased among zeolite-treated cows during the last 2 weeks of pregnancy but there was no effect on milk yield, milk fat, and milk protein in the subsequent lactation. The addition of zeolite to the daily ration during the last month of pregnancy prevented parturient paresis and subclinical hypocalcemia in

1638 1639

Jersey cows.[36] Feeding a vegetable oil supplement (soya bean oil) to pregnant pastured dairy cattle during the last 2–3 weeks of pregnancy is effective in preventing milk fever and increases milk solids production in early lactation.[37] The same supplement has been used to stimulate calcium absorption and reduction in susceptibility to fasting-induced hypocalcemia in pregnant ewes.[38,39] Following supplementation, the ewes are fasted overnight to challenge calcium homeostasis. Following fasting, there is a greatly increased capacity to absorb calcium.

29.2.4.11.1.1.4

Level of phosphorus in diet

Increased levels of dietary phosphorus, >80 g/head per day, can also increase the incidence of milk fever. The increased intake increases the serum level of phosphorus which has an inhibitory effect on renal enzymes. These enzymes catalyze the production of 1,25-$(OH)_2$ D, which when lowered will reduce intestinal calcium absorption. If the reduction of calcium is impractical, the lowering of phosphorus to below requirements may be beneficial.

29.2.4.11.1.1.5

Calcium and phosphorus ratio in diet

If the ration is low in calcium, the resulting negative balance of calcium can be expected to stimulate activity of the parathyroid gland. Early researchers made use of this physiological mechanism by feeding a high phosphorus/low calcium ration to cows during the last month of pregnancy. With a Ca:P ratio of 6:1, 30% of cows developed parturient paresis; at a Ca:P ratio of 1:1, 15% developed the disease; and at a ratio of 1:3.3, no cases occurred. Although there is no apparent effect on the subsequent lactation there is the possibility, if the negative balance of calcium is prolonged or repeated frequently, that such a ration may contribute to the development of osteoporosis. Dietary phosphorus concentrations can have an influence on calcium homeostasis.

29.2.4.11.1.2

Acidifying rations in the prepartum diet: Cation–anion difference (DCAD)

A more reliable method of controlling milk fever in dairy cows when the calcium intake exceeds NRC requirements is to manipulate the dietary cation–anion difference (DCAD) during the prepartum period.[11,40] Diets high in cations, especially sodium and potassium, tend to induce milk fever compared with those high in anions,

primarily chloride and sulfur, which can reduce the incidence. Because most legumes and grasses are high in potassium, many of the commonly used prepartum diets are alkaline resulting in metabolic alkalosis. The feeding of diets which are high in ratio of calcium to phosphorus and containing an excess of anions relative to cations will result in mild metabolic acidosis completely compensated by nonrespiratory mechanisms (decreased blood bicarbonate and base excess: Pco_2 and pH are unaffected).[41] There is increased concentration of serum calcium due to an increase in the intestinal absorption of calcium. Two parathyroid hormone (PTH) dependent functions, bone resorption, and renal production of 1,25-dihydroxyvitamin D, are enhanced in cows fed diets with added anions which increase their resistance to milk fever and hypocalcemia.[11]

Table 29.6 Molecular weights, equivalent weights, and conversions from percent to milliequivalents (%–mEq) of anions and cations used in calculating dietary cation–anion difference

Element	Molecular weight	Valence	Equivalent weight (g)	To convert from % diet DM to mEq. Multiply by: (mEq/kg)
Sodium	23.0	1	23.0	434.98
Potassium	39.1	1	39.1	255.74
Chloride	35.5	1	35.5	282.06
Sulfur	32.1	2	16.0	623.75
Calcium	40.1	2	20.0	499.00
Magnesium	24.3	2	12.2	822.64
Phosphorus	31.0	1.8	17.2	581.14

The DCAD is expressed using the equation DCAD in mEq/kg DM = (Na + K) – (Cl + S). The equation does not include other dietary cations and anions such as Ca^{2}, Mg^{2}, and PO_4 which have a minor role. Most studies indicate that a DCAD of – 50 to 100 mEq/kg DM is optimal for the prevention of milk fever.[1] Supplementation of diets in the last 3 weeks prepartum with anionic salts at a rate sufficient to decrease DCAD to – 15 mEq/100 g of dietary DM and urine pH to 6.0 prevented most cases of parturient

hypocalcemia.[42] Except for cows pregnant with twins, that rate of supplementation did not affect DM intake and energy balance. A moderate rate of supplementation to reduce the DCAD to 0 mEq/100 g dietary DM and urine pH to 7.3 also did not decrease feed intake or energy status but was less effective in preventing parturient hypocalcemia. Monitoring urine pH can be a useful aid to find the effective intermediate inclusion rate and it is suggested that a urine pH of about 6.5 is ideal.[42] Commercial anionic products fed to non-lactating dairy cows in a total mixed ration, after 4 days reduced urine pH below the desired threshold of 6.5.[43]

The equation assigns the same acidification potency to each mEq of Cl and SO_4, but Cl is absorbed to a greater extent than SO_4. Calculation of the DCAD of a diet requires use of the equivalent weights of the electrolytes. The equivalent weight is equal to the molecular weight divided by the valence. A milliequivalent (mEq) is used to express equivalent weights: 1 mEq equals 1/1000 of an equivalent. Table 29.6 provides reference values for calculating equivalent weights of important electrolytes and converting from percent diet dry matter (DM) to mEq/kg. Once mEq are calculated, the DCAD can then be determined by subtracting the anions from the cations.[31]

The DCAD is calculated from the percent element in the diet dry matter. The equation is as follows: mEq/100 g DM = [(% Na ÷ 0.023) + (% K ÷ 0.039)] – [(% Cl ÷ 0.0355) + (% S ÷ 0.016)]. Based on current evidence, the range which achieves the lowest incidence of milk fever is a DCAD of – 10 to – 15 mEq/100 g DM or – 100 to 150 mEq/kg DM.

Most typical diets fed to dry cows have DCADs of about 100–250 mEq/kg DM. Addition of a cationic salt such as sodium bicarbonate to the dry cow diets increases the DCAD and increases the incidence rate of milk fever. Adding an anion source or a mixture of anionic salts containing Cl and S relative to Na and K to the diet lowers the DCAD and reduces the incidence of milk fever. Commonly used sources of anion salts include the Cl and SO_4 salts of calcium, ammonium and magnesium. The phosphate salts have not been used because they are only weakly acidifying.

The addition of anions to the diet to reduce dietary DCAD is limited because of problems with palatability of the anionic salt sources commonly used. If the diet DCAD is >250 mEq/kg, it is difficult to add enough anionic salts to lower the DCAD to the recommended – 100 mEq/kg of the diet without affecting palatability.

1639 1640

In one study, the incidence of milk fever was 47% when prepartum cows were fed a ration with a DCAD of +330.5 mEq/kg dietary DM and 0% when the prepartum ration had a balance of – 128.5 mEq/kg dietary DM.[40] The incidence of milk fever was reduced by the addition of chloride and sulfur in excess relative to sodium and potassium in the diet.[40] Because anions are considered acidogenic and cations alkylogenic, an excess of acid-forming elements in periods of calcium stress will increase the concentration of calcium in the blood, either by intestinal absorption or bone mobilization.[31] Cows fed prepartum diets containing alfalfa haylage with added chlorides of magnesium, ammonia, and calcium tended to have higher plasma calcium concentrations of calcium and a lower incidence of milk fever than did cows fed either of two cationic diets. Plasma hydroxyproline, an index of bone resorption, also increases prior to parturition in cows fed a high anion diet. The plasma levels of 1,25-$(OH)_2D$ also increase prior to parturition in cows fed a high anion diet, which increases calcium absorption and bone resorption.[31] Feeding rations with reduced mEq of dietary ($[Na^+ + K^+] – [CI^- + SO_4=]$) to – 4 mEq/kg dietary DM to dry cows significantly affected some of the parameters of bone formation but did not enhance the rate of bone resorption. Feeding acid diets to pregnant cows during the last 28 days of pregnancy increased the mobilization of calcium by 13% 14 days before parturition and 28% by the time of parturition, whereas it had declined by 14% at 14 days before parturition in alkali-fed cows. The increased concentrations of 1,25-$(OH)_2D$ were responsible for the stimulation of both intestinal calcium absorption and bone resorption, which helped to prevent severe parturient hypocalcemia.

29.2.4.11.1.2.1

Anion salts for acidification of prepartum diets for dairy cows

Several anion salts are available for addition to the ration of prepartum dairy cows to prevent milk fever.[44] Generally, acidification of the cows occurs in approximately 36 h following addition of the anionic salts to the ration; it also takes less than 36 h for the cow to return to an alkaline state following removal of the salts from the diet. The relative acidifying activity of anionic salts commonly used to prevent milk fever has been evaluated.[44] Salts of chloride have about 1.6 times the acidifying activity of sulfate. Calcium and magnesium, which are usually not included in the DCAD equation, have a small but significant alkalinizing effect when accompanied by chloride or sulfate. The ranking of the anion sources tested at a dose of 2 Eq/day, from most to least potent urine acidifier was ***hydrochloric acid, ammonium***

chloride, calcium chloride, calcium sulfate, magnesium sulfate, and sulfur. Magnesium sulfate is the most palatable of the anionic salts commonly supplemented and calcium chloride is the least palatable. Sulfates are poor acidifiers and should be limited in use. It is best to add the anionic salts to a total mixed ration. Because of the low incidence of milk fever in heifers there is no need to feed anionic salts to heifers.[42]

Anionic salts can reduce dry matter intake when more than 300 mEq of anions/kg diet DM are supplemented in the diet.[31] The reductions in dry matter intake are commonly ascribed to decreased palatability but may represent a response to the metabolic acidosis induced by the salts.[41] The duration of feeding anion salts ranges from 21 to 45 days before expected parturition. At least 5 days of consumption are necessary for maximal benefit.

29.2.4.11.1.2.1.1

Ammonium chloride.

Ammonium chloride is more effective than most other salts as an acidifier. The addition of ammonium chloride salts to prepartum diets offers considerable promise as a practical and reliable method of control of milk fever. Experimentally, the addition of ammonium chloride and ammonium sulfate, each at 100 g/head per day, to the prepartum diets 21 days prior to parturition, decreased the incidence of milk fever from 17% in the unsupplemented group to 4% in the supplemented group.

The advantages of ammonium salts are that they:

- Do not require the use of diets low in calcium
- Are relatively inexpensive
- Are convenient to use
- Are safe to feed.

29.2.4.11.1.2.2

Strategies for supplementing anion sources

A systematic protocol for the addition of anions to a prepartum diet and monitoring its effects is as follows:

1. Macromineral analysis of all available forages for prepartum cows.

2. Select feed ingredients with a low DCAD especially those low in potassium.
3. Calculate the DCAD of the diet without any supplemental anion sources. If the DCAD is more than 250 mEq/kg, then it is too high. Replace some of the forage with a lower DCAD forage.
4. Balance dietary magnesium at 0.40%, DM by adding additional magnesium chloride or magnesium sulfate. Magnesium chloride is preferred.
5. Evaluate the feeding management of the prepartum cows. Ensure adequate feeding space and quality of feed.
6. Add supplemental chloride to the prepartum cow diet to lower DCAD to about – 150 mEq/kg DM.
7. Evaluate dietary non-protein nitrogen (NPN) and degradable intake protein (DIP) of the diet. If NPN is more than 0.50% of the diet DM or DIP is more than 70% of crude protein, then reduce the amount of ammonium salts or other NPN or DIP sources in the diet.
8. Elevate the dietary calcium to 1.5–1.8% DM or provide daily intake of about 150 g/head per day. Negative DCAD diets increase urinary calcium excretion and thus more dietary calcium is necessary to meet requirements.
9. Monitor dry matter intake of the prepartum cow group. Consider more palatable anion sources or a reduced dose of anion sources if dry matter intake is depressed. Low dry matter intakes in prepartum cows increases the risk for fatty liver and ketosis after calving.
10. After 1 week of feeding anionic salts, monitor the pH of close-up dry cows. Urinary pH is an accurate indication of optimal dietary acidification. Collect urine from at least six cows at one time and average the urinary results. Adjust the dose of supplemental anions to achieve an average urinary pH of between 6.0 and 7.0.

29.2.4.11.1.2.3

DCAD and acid–base balance of dairy cows on pasture-based diets

The literature on the nutritional strategies for the prevention of hypocalcemia for dairy cows in pasture-based systems has been reviewed.[6] The dairy industries of southern Australia and New Zealand are based largely on fresh pasture and pasture silage and grazed pasture is the key determinant of the DCAD. The concentration of potassium is often in excess of 4% and the DCAD >500 mEq/kg DM, in pasture-based diets yet the incidence risk of milk fever is not higher than those in other countries where dietary potassium is much lower. For a considerable part of spring and early summer, the DCAD of pasture in those countries may be in excess of +500–700 mEq/kg DM.[5,29] The variation in the DCAD of pasture and the difficulty in accurately assessing dry matter intake makes an accurate reduction in DCAD difficult to achieve practically.[5,45] Pasture cation–anion difference in those conditions is not greatly influenced by stocking rate or associated management practices. The urine pH of grazing dairy cows in south-eastern Australia remains relatively constant throughout the year despite changes in stage of lactation, management practices, season, weather, and large changes in DCAD. It appears that a very low DCAD (< + 150 mEq/kg DM is required to alter systemic pH substantially. The DCAD of pasture throughout the year in south-eastern Australia ranges from 0 to 800 mEq/kg DM and is often outside the levels previously recommended for optimal performance of lactating cows. A high DCAD at the time of parturition, for spring-calving herds on pasture, presents practical problems in administering the large amounts of anionic salts required to lower urine pH and to decrease the incidence of hypocalcemia.[5,29]

The dietary cation–anion difference and the health and production of pasture-fed dairy cows in early lactation in southeastern Australia has been examined in an indoor feeding experiment.[46] The dairy industry there is largely perennial ryegrass-based and supplemented with cereal grains, pasture hay, and pasture silage. The DCAD can range from 0 to + 76 mEq/100 g. Blood pH and urine pH are reduced when a low DCAD ration is fed, but there is a threshold level, between + 52 and + 102 mEq/100 g, above which little change in systemic pH occurs.[46] As DCAD increased from + 21 to +127 mEq/100 g, DMI intake and milk yield decreased. In nonlactating periparturient cows fed freshly cut pasture supplemented with varying

levels of salts to alter the DCAD which ranged from – 12 to + 69 mEq/100 g.[47] With decreasing DCAD, the pH of the blood and urine decreased resulting in a nonrespiratory systemic acidosis. When the DCAD was negative, the urinary output of calcium increased. No differences in milk production due to alteration of the DCAD. Due to the high DCAD in the base diet offered to pasture-fed dairy cows and the requirement for a negative DCAD to increase calcium absorption, it is unlikely that the DCAD concept is a practical means of preventing milk fever in pasture-fed cows.

In these pasture-based systems, sulfur (S) is considered a more important dietary constituent in determining the risk of hypocalcemia than either chloride or potassium.[45] The absorption efficiency of S is less than either Cl or K and would not be expected to incur the same change in systemic pH. Thus its importance in hypocalcemia prevention, does not fit with the current understanding of how manipulation of DCAD influences calcium homeostasis. Studies indicate that pre-calving dietary S is more important in the control of hypocalcemia than either K or Cl concentration. Although the effects of a systemic acidosis on Ca absorption is accepted, the effect of S on periparturient Ca homeostasis when absorption of S is low in comparison to Cl, Na, or K suggest that there are mechanisms involved that are not related to acid-base balance. Dietary S concentration was more important in the control of hypocalcemia than either dietary K or Cl concentration.

An increased incidence of milk fever may occur in pastured-based dairy when the diet is supplemented with Cl and S, even though calcium absorption, as indicated by urine calcium concentration increases. The increased incidence may be due to a greater demand for dietary calcium after calving following a reduction in the pH of body fluids pre-calving and the fact that pasture-based diets, as opposed to total mixed rations, are generally low in calcium. Supplementation of cows with calcium after calving increased plasma calcium concentration on the day of calving and during the subsequent 14 days.[48] Milk production was not affected by pre- or post-calving treatments.

Experimentally, the application of potassium fertilizer on pasture resulted in a DCAD ranging from 350 to 535 mEq/kg DM but calcium homeostasis in pasture-based dairy cows was not changed.[45] Plasma concentrations were increased and the risk of clinical periparturient hypocalcemia was reduced by $MgCl_2$ and $MgSO_4$ delivered by 150 g $MgCl_2$, 200 g $MgSO_4$, and 35 g MgO/head daily for 21 days

prepartum.[45] After calving cows were supplemented with 150 g $CaCO_3$/head per day for 4 days. Improvements in calcium homeostasis were not due to an altered systemic pH.

The optimum DCAD for lactating cows grazing fresh pasture and the effect of deviating from the optimum on milk production has been examined under experimental manipulating the dietary DCAD using a drench in early-lactation dairy cows in New Zealand.[49] Dietary cation-anion differences ranged from + 23 to + 88 mEq/100 g of DM. As DCAD increased, there was a linear increase in blood pH and HCO_3 concentration and blood base excess. Plasma concentrations of Mg, K, Cl declined as DCAD increased and Na increased. Urinary excretion of Ca decreased as DCAD increased. Increasing DCAD did not significantly affect milk yield or milk protein but the concentration and yield of milk fat increased linearly. Milk production results suggest that DCAD for optimal production on pasture diets may be higher than the +20 mEq/100 g DM previously identified for total mixed rations.

29.2.4.11.1.2.4

Summary of macromineral nutritional strategies for the prevention of hypocalcemia in the soon-to-calve, or transition dairy cow in pasture-based systems. (Transition period is defined as 3–4 weeks prepartum and 3–4 weeks postpartum)

Circumstances and principles:

- When dairy cows are dried off, they are commonly moved onto nonirrigated pastures until calving. In the summer, dry cows would be put onto actively growing tropical pasture, whereas in autumn, winter and spring, the pasture is most likely to be tropical pasture carried over from the previous summer. This carryover pasture is likely to be supplemented with medium quality hay, silage and grain or molasses 2–3 weeks before calving. Anionic salts have been added to these diets
- The DCAD on a yearly basis ranges from 0 to 80 mEq/100 g DM[5]
- The incidence of milk fever in Australia ranges from 1.6 to 5.4% but in some years, the incidence in individual herds may reach 20%. The incidence of subclinical hypocalcemia can range widely; up to 40% of apparently normal

cows had subclinical hypocalcemia (total plasma calcium <1.9 mmol/L during the first 12 days of lactation)

- The concentration of ionized calcium in blood plasma is under elaborate homeostatic control. This provides for the maintenance of a pool of readily available calcium which can be drawn on for the deposition of maternal and fetal bone and for colostrum and milk
- The traditional method of preventing hypocalcemia has been to restrict calcium intake during the dry period which stimulates renal synthesis of 1,25-dihydroxyvitamin D_3 prior to calving. The cow must be in negative calcium balance
- In temperate climates, reducing dietary calcium to recommended low levels can be difficult to achieve but in tropical pastures the levels are already low
- Excessive levels of potassium may be the most important dietary risk factor for milk fever in Australian feeding systems. Potassium contents of pastures may be as high as 4–5% of DM. The use of potassium fertilizers exacerbates the problem. Potassium and dietary DCAD peak in winter and are lowest in autumn. The majority of cows in Victoria, Australia, calve in winter to early spring when the potassium levels are high. Excess potassium results in alkalosis which reduces the sensitivity of bone and renal tissue to PTH

1641

1642

- Hypomagnesemia influences calcium homeostasis and diets high in potassium reduce the concentration of plasma magnesium. Magnesium supplementation of the transition diet should be done to ensure that magnesium requirements are met (0.2–0.4% of DMI)
- Excessive dietary phosphorus increases the concentration of phosphorus in plasma which can induce hypocalcemia and increase the incidence of milk fever at calving. Supplements likely to increase the dietary intake of phosphorus above 35 g/day should not be fed to cows in the weeks prior to calving
- Excessive intakes of sodium can contribute to the development of metabolic alkalosis and should be avoided.

Options for reducing the risk of hypocalcemia in pasture-fed dairy cows:

29.2.4.11.1.2.4.1

Low calcium intake prepartum.

A low calcium diet in the prepartum period will activate calcium homeostasis at calving. An alternative is to feed calcium binding agents for 1–3 weeks prepartum.

29.2.4.11.1.2.4.2

Magnesium supplementation.

Hypomagnesemia influences calcium homeostasis, potentially predisposing the cow to milk fever at calving. Diets high in potassium can reduce the concentration of plasma magnesium and may be a mechanism linking high dietary potassium to hypocalcemia. Recommended concentrations for dietary magnesium levels are within the range of 0.2–0.4% of total DM intake. Plasma levels are readily elevated when magnesium is added to the diet.

29.2.4.11.1.2.4.3

Calcium supplementation.

Oral administration of gels of calcium chloride or calcium propionate immediately after calving is effective in preventing milk fever. Feeding cows an excess of calcium in the form of calcium carbonate during the first few weeks of lactation is beneficial. Increasing dietary concentration of calcium from 0.68% to 1.02% DM within 8 h of calving has an immediate effect on plasma calcium.[6]

29.2.4.11.1.2.5

Manipulating dietary DCAD with anion feeds

The concept of manipulating the DCAD to reduce hypocalcemia under North American and European circumstances is well documented.[6] Addition of anionic salts to the diet of transition dry cows to achieve a metabolic acidosis improves the ability of the cow to mobilize calcium at parturition. The pH of both blood and urine consistently fall in response to an appropriate decline in dietary cation excess. For the transition dry cow, the DCAD must fall to between – 10 and – 15 mEq/100 g DM to prevent milk fever.

In pasture-fed systems, such as in Australia and New Zealand, the pasture diets are high in DCAD (+ 50 mEq/100 g DM). The more positive the pasture DCAD, the more difficult it is to balance it with anionic salts. Because anionic preparations are relatively unpalatable, cows will not eat enough for total DCAD to fall below 0 mEq/100 g DM.

An alternative to anionic salts is to select feedstuffs with low to moderate DCAD. Lower quality hays and straws have a lower DCAD than high quality forages. However, the feedstuffs must be analyzed before making such a recommendation. Lower quality roughages are also low in calcium. Concentrates with high negative DCAD include molasses and brewer's grain. Molasses is high in potassium but also high in sulfur.

Measurement of urine pH as a method of monitoring the efficacy of DCAD manipulations and its on-farm use should be encouraged. Urine pH is unlikely to fall to any degree until DCAD of the diet drops below approximately 10–20 mEq/100 g DM. For protection against milk fever, the urine pH needs to be maintained between 5.5 and 6.2 in the last weeks before calving.[1] This could be reduced to a cut-off in the range of pH 6.5–7.0.[13,31]

29.2.4.11.1.3

Calcium gel dosing

The oral administration of easily absorbed calcium salts such as calcium chloride providing 40–50 g calcium per dose as a bolus, a gel, a paste or a liquid, given in 3–4 doses beginning 12–24 h before calving, to 24 h after calving will prevent a significant proportion of milk fever cases.[30] The oral administration of one or two doses as a supplement to intravenous calcium borogluconate is also effective in reducing the incidence of relapses. Calcium chloride is caustic and can cause oral lesions. The use of calcium formate (350 mL of 48.6% aqueous suspension), four times at approximately 12 h intervals, had no adverse effects on cows and is considered a safe form of calcium supplementation on adult dairy cows.[50] Oropharyngeal abscesses secondary to trauma and laceration caused by the administration of the boluses may occur.

29.2.4.11.1.4

Vitamin D and its metabolites or analogs

Vitamin D_3 (cholecalciferol) administered parenterally was historically, a popular prophylactic against milk fever. However, because of the potential for toxicity of vitamin D injections and expense of its analogs, these are no longer used. The literature on the role of vitamin D in calcium homeostasis and its use in the prevention of periparturient paresis in cattle has been reviewed.[6] Their uses are summarized here and advantages and disadvantages outlined.

In an attempt to reverse the negative calcium balance of susceptible cows the administration of vitamin D and its analogs have been used to increase intestinal absorption of calcium. Vitamin D_3 is hydroxylated in the liver and the resulting metabolite is 25-hydroxycholecalciferol. This is metabolized in the kidney to 1,25-dihydroxycholecalciferol, which has an active hypercalcemic effect but is difficult to synthesize. One of its analogs, 1-α-hydroxycholecalciferol is as active, is easy to prepare, and is used pharmacologically.

Oral dosing with vitamin D_2 and the parenteral administration of vitamin D_3 and dihydrotachysterol all have their proponents. Oral dosing with 20 million IU of vitamin D_2/d for 5 days to cows immediately prior to calving can markedly reduce the expected incidence of milk fever. The exact date of calving is often difficult to determine and if the administration is discontinued for up to 4 days before calving, an unusually high incidence of the disease may follow, probably because of the depression of parathyroid activity which follows the administration. The danger of causing metastatic calcification also exists as this has been produced with smaller doses (10–20 million IU daily for 10 days). Pregnant cows are more susceptible to calcification than non-pregnant animals. Treatment with larger doses or for longer periods than those recommended earlier should be avoided because of the danger of toxic effects. Smaller doses reduce the risk of calcification but also reduce the degree of calcium retention.

A single dose of 10 million IU of vitamin D_3 IM given 2–8 days before parturition has been considered as optimal. A dose of 1 million units per 45 kg BW has given consistently better results. This may explain the variable results and why results have been more favorable in Jersey cattle. If the cow fails to calve after the 8th day, another 10 million units may be administered and repeated every 8 days until the cow calves. Subclinical calcification may occur in vessel walls but this is unlikely if dietary calcium and phosphorus intake is adequate. Single doses of 40 million units of vitamin D can be lethal. One of the disadvantages of this method is the likelihood that cows which do not calve at the anticipated time can be more seriously affected than if they receive no treatment. The hypercalcemic effect of cholecalciferol by injection is very much longer when it is administered by IM injection (up to 25 days) than by IV injection (up to 3 days) for this reason and because occasional cases of shock occur after the IV administration, especially if more than one injection is given, the IM route

is preferred. The injection of vitamin D is preferred to feeding it and a protection rate of up to 80% can be anticipated. It is estimated that 95% of Jersey cattle are protected.

Other compounds with vitamin D activity but which avoid the possibility of causing hypervitaminosis D and are therefore useful in the prevention of milk fever are:

- **25-Hydroxycholecalciferol** injected IM at 8 mg 3–10 days before calving and repeated at weekly intervals. Single doses of 4 mg are not effective in reducing the occurrence of parturient hypocalcemia or milk fever.
- **1,25-Dihydroxyvitamin D_{35}** given at 200 μg daily, orally, to calving cows reduces the development of hypocalcemia but does not completely prevent milk fever. When 1,25-$(OH)_2D$ is given IM between 1 and 4 days of calving, it is effective in preventing milk fever. When administered less than 24 h or more than 4 days before calving, parturient paresis is not effectively prevented. Repeated injections at 4–7 day intervals until calving can be used, but toxicity can be a problem. A third problem with this metabolite is that the IM injection can result in milk fever 1–2 weeks after parturition because the exogenous metabolite may inhibit the endogenous production in some cows and when the exogenous product is cleared from the body, the cow is unable to produce sufficient 1,25-$(OH)_2D$ to maintain enhanced intestinal absorption of calcium.
- **24-F-1,25-dihydroxyvitamin D_3** given at 100–150 μg 5 days before the expected date of parturition was effective.[23] Cows which did not calve within 7 days were given a second dose. The incidence of milk fever in untreated controls, those receiving 100 and 150 mg, was 85%, 43%, and 29%, respectively. The use of SC-released product implanted 7 days before parturition and repeated at 7 day intervals until calving resulted in milk fever in 80% of controls and 9% in treated cows. The SC pellet maintained levels of the vitamin D metabolite for about 10 days, compared with the IM injection, which results in very high concentrations in the plasma in the first 48 h after injection.
- **1-α hydroxyvitamin D_3** at 350 μg IM is effective as a preventive to milk fever if given 72 and 24 h before parturition. If calving has not occurred naturally within 72 h, a second injection is given. Parturition is induced if calving has not occurred 2 days after the second injection. The preferred site of injection is the serratus muscle of the neck, which results in a more effective response. To avoid the problems created by cows not calving at the predicted time, a combined

regimen including induction of parturition by the administration of corticosteroid with the injection of 1-α-hydroxycholecalciferol is reported to be successful. Injection of cows with the same vitamin D analog plus a prostaglandin (cloprostenol) was unsuccessful in preventing milk fever. A dose of 700 μg given 6–8 days before calving is also recommended. Another recommendation suggests 500 μg at 2–5 days prior to parturition. An evaluation of routine use of 1-α-hydroxyvitamin D_3 indicated that cows which developed retained placenta and metritis may be at greater risk of not conceiving within 150 days from calving. There is some transfer of the metabolite from the maternal to fetal plasma. Injection within 24 h of the onset of milk fever is ineffective, but if it is given more than 24 h and less than 1 week before the onset of the disease, the protection is excellent.

29.2.4.11.2

General management practices

The following management practices are suggested:

- Avoid overfattening by either reducing the energy concentration of the ration or restricting the intake during the prepartum period. This also appears to stimulate appetite, thus keeping cows on feed
- Avoid stresses at the time of parturition
- Provide a clean well-bedded box stall with conditions conducive to cow comfort and allow the animal to exercise
- Make frequent observations of cows prone to milk fever from 48 h before to 48 h after parturition for evidence of milk fever and ***immediate treatment*** will reduce the incidence of the downer cow syndrome associated with milk fever
- At calving the cow should receive an oral dose of a calcium salt in a gel, as set out later, followed by a diet with a high calcium content (over 1% of dry matter). The critical day is the day of calving and a sharp increase in calcium intake on this day can significantly reduce the occurrence of milk fever
- If hypomagnesemia is a likely concomitant, the diet should be supplemented with 60 g magnesium oxide daily.

29.2.5 DOWNER COW SYNDROME (NON-AMBULATORY COWS WITH NON-PROGRESSIVE NEUROLOGICAL FINDINGS)

29.2.5.1 Synopsis

29.2.5.1.1 Etiology

Ischemic necrosis of large muscles of pelvic limbs secondary to prolonged recumbency associated with milk fever. Other causes of recumbency can also result in downer cow syndrome.

29.2.5.1.2 Epidemiology

Most common in dairy cows which have had milk fever but are unable to stand following treatment with calcium. Delay of more than 4 h in treatment for recumbent milk fever cows. Hypophosphatemia and/or hypokalemia may be risk factors.

29.2.5.1.3 Signs

Unable to stand following treatment for milk fever. Sternal recumbency. Normal mental status, vital signs and alimentary tract. Appetite and thirst normal. Most will stand in few days if provided good clinical care and secondary muscle necrosis minimized. Some cases have bizarre behavior of lateral recumbency, abnormal position of legs, groaning, anorexia, and die in several days.

29.2.5.1.4 Clinical pathology

Increased serum levels of creatine phosphokinase (CPK) and aminotransferase (AST); serum phosphorus and potassium levels may be subnormal.

29.2.5.1.5 Necropsy findings

Ischemic necrosis, edema and hemorrhage of large medial thigh muscles.

29.2.5.1.6 Diagnostic confirmation

Increased serum levels of CPK, AST, proteinuria; necropsy lesions in cow unable to rise with no other lesions.

29.2.5.1.7

Differential diagnosis list

- See differential diagnosis of milk fever and Table 29.5.
- Common causes of recumbency in dairy cows around time of parturition include:
- Milk fever
- Hypomagnesemia
- Peracute coliform mastitis
- Maternal obstetrical paralysis
- Fat cow syndrome
- Physical injuries of pelvic limbs (dislocation of hip joints, rupture of gastrocnemius, femoral fracture)
- Acute diffuse peritonitis (ruptured uterus, other causes).

29.2.5.1.8

Treatment

Provide feed and water and excellent bedding or ground surface like sand or dirt pack. Roll animal from side to side every few hours. Fluid and electrolyte therapy as necessary.

29.2.5.1.9

Control

All recently calved dairy cows which are at high risk for milk fever must be observed closely 12 – 24 h before and after calving for evidence of milk fever and while still standing; if recumbent do not delay treatment for more than 1 h. Can treat all high-risk cows with calcium chloride gel orally to prevent clinical milk fever.

29.2.5.2

ETIOLOGY

Most commonly, the downer cow is a complication of milk fever.[1] Ischemic necrosis of the large muscles of the pelvic limbs and injuries to the tissues around the hip joint and of the obturator muscles are common in cows which do not fully recover and stand but remain recumbent following treatment for milk fever. Injuries to the musculoskeletal system are also common as a result of cows ‘spread-eagling' their hindlimbs if they are

unsteady during parturition or forced to stand or walk on a slippery floor immediately before or following parturition. Dystocia due to an oversized calf may result in extensive edema of the pelvic tissues and vulva, and failure of the cow to stand following parturition. If these cows develop milk fever, it is unlikely they will be able stand following treatment with calcium.

29.2.5.3

EPIDEMIOLOGY

29.2.5.3.1

Occurrence

The disease occurs most commonly within the first 2 or 3 days after calving in high-producing dairy cows immediately following milk fever. Cattle may also become persistently recumbent for many reasons other than complications of milk fever such as peracute coliform mastitis and carbohydrate engorgement.

Downer cows can be divided generally into non-ambulatory cows with non-progressive neurological findings and non-ambulatory with progressive neurological findings indicative of the presence of lesions in the nervous system as the cause of the recumbency.[2]

A survey of bovine veterinarians in the USA in 1998 collected data on non-ambulatory dairy and beef cows with non-progressive neurological findings, and non-ambulatory with progressive neurological findings.[2] Of the population studied, 0.25% developed a non-ambulatory non-progressive neurological disorder for a case rate of 066 animals/10^6 cow years or 10^6 cows/year. Of these, 74.3% failed to recover. In non-ambulatory dairy cows with non-progressive neurological findings, 85% of cases fit into three categories: injury/trauma, septicemia/toxemia, or non-responsive milk fevers. Of the total, 3.3% remain undiagnosed. In non-ambulatory beef cows with non-progressive neurological findings, trauma/injury, septicemia, and other neurological cases accounted for 78% of cases. Of the population studied, 0.12% of cows developed non-ambulatory non-progressive neurological findings syndrome for a case rate of 2476/10^6cows. Of the total, 73% failed to recover. Of the beef cows, 0.0053% remain undiagnosed, which implies that 4.3% of all beef cows with non-ambulatory non-progressive CNS findings were unknown and undiagnosed and 96% were diagnosed.

Of the total number of non-ambulatory progressive CNS cases reported for dairy cattle, the percentage was 0.027% for a case rate of 554/10^6. Of these, 17.7% were unknown or

undiagnosed indicating that 82% of progressive CNS dairy cattle cases were diagnosed. The progressive CNS cases of unknown cause represented 0.0047% of the study's cattle population, or a rate of 94 cases/10^6 dairy cows. Seventy-one of the cases failed to recover for a mortality of 375 cases per million dairy cows in the study.

The profile of a progressive CNS dairy cow case found that other known CNS diseases, septicemia/toxemia, unknown CNS diseases, and non-responsive milk fever to be the most frequently reported cases.

Of the total number of non-ambulatory progressive CNS cases reported in beef cattle, the percentage was 0.018%. Of these, 9.0% were of unknown etiology indicating that 91% of progressive CNS beef cow cases were diagnosed by veterinarians. The unknown progressive CNS case rate was 32 cases/10^6 beef cattle. The total deaths in progressive CNS cases accounted for a mortality rate of 282/10^6.

The profile of progressive CNS beef cow cases found that four categories accounted for 83.4% of the total causes: injury/trauma, known infectious agent, septicemia, toxemia, and known CNS disease.

29.2.5.3.2

Incidence

The incidence as a complication of milk fever is high because many affected animals are high producers and of high economic value. Accurate data on the incidence are not available because of variations in the nomenclature used and the accuracy of diagnoses. For example, some observations report that all cases are caused by nerve injury.[3] Cases included in this classification are classified by others as maternal obstetric paralysis, obturator paralysis, or hypophosphatemia. Because it is a syndrome lacking in clinical definition and includes all those ‘other cases' which cannot be otherwise classified, the incidence varies depending on the clinical acuity of the individual veterinarian, and on various environmental factors in different areas. However, the incidence seems to be increasing, particularly in intensive dairy farming areas, although this impression could arise from the increased necessity to effect a cure in valuable animals.

1644 1645

A mail survey of 723 dairy herds in Minnesota found a downer cow incidence of 21.4/1000 cow years at risk.[3] The overall outcome was that 33% recovered, 23% were slaughtered and 44% died. The owners perceived that downer cows were high producers (48%) or average producers (46%), with only 6% being low producers. Approximately 58% occurred within 1 day of parturition and 37% occurred during the first 100 days of

lactation. The incidence was highest (39%) during the three coldest months: December, January, and February. In New Zealand, the prevalence ranges from 3 to 5% of all dairy cows at calving time.[4]

In a clinical and laboratory survey of 433 periparturient recumbent cows in New Zealand, 39% recovered, 30% died, and 32% were destroyed.[4] The case-fatality rate was 11% higher in pre-calving recumbent cows than post-calving cows.

An audit of 21 slaughter plants in the USA in 1993 found 1.1% of arriving dairy cows were non-ambulatory, and in 1999, 1.5%.[5] In 1993, 1.0% of beef cows arriving at slaughter plants were non-ambulatory and in 1999, 0.7%.[5]

29.2.5.3.3 Risk factors

29.2.5.3.3.1 Animal risk factors

29.2.5.3.3.1.1 Complication of milk fever.

Prolonged recumbency after a long delay in the treatment of milk fever is a major risk factor. Prolonged recumbency before treatment for milk fever (more than 4–6 h) results in ischemic necrosis due to obstruction of the blood supply, especially in a heavy cow if she lies on one leg for a long period.[6] Cows which develop milk fever while in a standing tie-stall may slide backwards into the gutter behind the stall, resulting in extreme pressure to their pelvic limbs and leading to ischemic necrosis.

A case-control study to identify risk factors for the development of downer cow syndrome within 30 days post partum in 12 dairy herds over 2705 lactations found that clinical hypocalcemia and stillbirth increased the risk of the disease five-fold.[7] Cows with retained placenta and dystocia were also more likely to develop downer cow syndrome than cows without either problem.

A marked increase in the CPK levels in cows with milk fever and failure to stand after repeated treatments is supporting evidence for ischemic necrosis associated with prolonged recumbency as a major cause of downer cow syndrome.[1] The CPK levels increase markedly between the first and second treatments, which indicates that muscle damage has occurred and the levels are highest in cows which do not recover.

Experimentally, enforced recumbency of cattle for 6, 9, or 12 h with one hindlimb positioned under the body results in downer cow syndrome. Affected cows are unable to stand and the affected limb is swollen and held rigid similar to the injured limbs of human patients with compartmental/crush syndrome.

Surveys have shown that downer dairy cattle have 3.3-fold-higher prevalence of *E. coli* 0157:H7 than healthy cattle within a certain time frame and geographic area.[8] Culled dairy cows account for approximately 17% of the ground beef produced in the US and thus downer cattle harboring *E. coli* 0157:H7 may be an important source of contamination of ground beef which is commonly processed from downer cattle.

29.2.5.3.3.1.2

Traumatic injuries to pelvis and pelvic limbs.

Traumatic injuries to the nerves of the pelvis and hindlimbs are present in 25% or more of downer cows.[1] The sciatic and obturator nerves are vulnerable to injury by pressure from the calf moving through the pelvic canal during parturition. Pressure injuries on the superficial nerves (radial and peroneal) of the extremities also occur in recumbent cows.

29.2.5.3.3.1.3

Serum electrolyte imbalances.

Serum electrolyte imbalances or deficits may be associated with prolonged recumbency following treatment for parturient paresis.

29.2.5.3.3.1.4

Hypocalcemia.

A persistent hypocalcemia following treatment for milk fever may exist in a downer cow but is unlikely to be the principal cause because treatment with calcium salts does not resolve the signs, even temporarily. However, the use of an insufficient amount of calcium for the initial treatment of milk fever in large, heavy cows may result in an incomplete response and failure of the cow to stand. If these cows are not retreated soon enough with an adequate amount of calcium, ischemic necrosis of the limb muscles occurs and leads to prolonged recumbency. In many cases, even after the cow is given a sufficient amount of calcium, prolonged recumbency occurs due to the ischemic necrosis.

29.2.5.3.3.1.5

Hypophosphatemia.

The serum levels of inorganic phosphorus decline to below normal along with a hypocalcemia in cases of milk fever. Following treatment of milk fever with calcium borogluconate, the levels of serum calcium and phosphorus return to normal if the animal responds favorably and stands normally. Following treatment for milk fever, some cows do not or are unable to stand and their serum phosphorous levels are subnormal. This persistent hypophosphatemia has been regarded as a cause of downer cow syndrome associated with milk fever. Many veterinarians claim that these cows respond to treatment with phosphorus. However, persistent recumbency is associated with subnormal levels of serum phosphorus which increase to normal if the cow stands regardless of treatment with or without phosphorus. Mature dairy cows may become recumbent in early lactation and subnormal levels of serum phosphorus may be present.[9] Other cows in the herd may be lame due to demineralization of bones associated with a dietary deficiency of phosphorus.

29.2.5.3.3.1.6

Hypomagnesemia.

A long-term low-level hypomagnesemia has been associated with the downer cow, especially when it accompanies hypocalcemia. But it is usually manifested by a tetanic hyperesthetic state which is not part of downer cow syndrome. Hypokalemia is, with hypophosphatemia, the most commonly quote cause, especially in the so-called ‘creeper' cows, which are bright and alert and crawl about, but are unable to rise.[10]

29.2.5.3.3.1.7

Hypokalemia.

Ischemia due to prolonged recumbency associated with milk fever, may increase the cell membrane permeability of muscle fibers and allow the loss of potassium from the cell; this in turn causes the myotonia, which appears to be the basis of downer cow syndrome. This view is supported by the low serum and muscle potassium levels in downer cows. Claims are made that potassium salts are successful in treatment but these have been difficult to evaluate.[4]

Hypokalemia occurs in dairy cows which have been treated with isoflupredone acetate for ketosis.[11] Affected animals are weak, recumbent and severely hypokalemic with serum potassium levels ranging from 1.4 to 2.3 mEq/L.

29.2.5.3.3.2

Environmental and management risk factors

A slippery ground surface is a major risk factor. Cattle which must walk across slippery floors, especially at the time of calving, may slip and fall and injure the large muscles of the pelvic limbs, resulting in an inability to stand. Prolonged recumbency results in ischemic necrosis and downer cow syndrome.

29.2.5.3.4

Summary

Downer cow syndrome is a complication of the recumbency associated with milk fever. A delay of 4 h or more in that treatment of cows with milk fever may result in ischemic necrosis of the muscles of the pelvic limbs. Traumatic injury to leg muscles at the time of parturition or when the cow is unsteady and falls during the first stage of milk fever will also result in the inability of the cow to stand following treatment of milk fever. 1645 1646

29.2.5.4

PATHOGENESIS

Several different primary factors or diseases can result in recumbency.

29.2.5.4.1

Prolonged recumbency before treatment

A long delay in the treatment of milk fever can result in pressure damage and the subsequent inability to stand after treatment for the primary disease. Prolonged recumbency results in pressure damage, which occurs secondarily and is a factor common to all cases.[3]

Regardless of the cause, the prolonged recumbency results in varying degrees of ischemic necrosis of major muscles of the hindlimbs, particularly the semitendinous muscle and muscles caudal to the stifle. Prolonged compression of the muscle leads to tissue anoxia, cell damage and inflammation which causes swelling; the swelling causes a further increase in pressure which limits tissue perfusion and leads to a detrimental cascade of events. The thick fascial boundaries of the semitendinous muscle prevent expansion which results in pressure-induced compartmental syndrome. Sciatic nerve

damage due to pressure also occurs and may contribute to downer cow syndrome. Experimental external compression of the pelvic limb of the goat, to simulate limb compression in recumbent cows, resulted in a marked reduction in nerve condition velocity of the peroneal nerve which was associated with clinically evident limb dysfunction. Damage to the peroneal nerve will result in hyperflexion of the fetlock if and when the cow is able to stand.

Traumatic injury to limb muscles and nerves immediately prior to parturition or at the time of parturition can also result in prolonged recumbency and subsequent pressure damage.[1]

29.2.5.4.2

Experimental sternal recumbency

Experimentally induced sternal recumbency with one hindlimb positioned under the body to simulate prolonged recumbency will result in a swollen rigid limb within 6–9 h.[12] Following injury to the muscle cells, the serum levels of CPK are markedly elevated at about 12 h after the onset of recumbency. Proteinuria and in some severe cases myoglobinuria occur between 12 and 36 h after the onset of prolonged recumbency, due to the release of myoglobin from damaged muscles. In cows which make efforts to stand but cannot do so, continued struggling results in rupture of muscle fibers and hemorrhage which increases the severity.

Acute focal myocarditis may occur in about 10% of cases resulting in tachycardia, arrhythmia, and the unfavorable response to IV calcium salts observed in some cases. The cause of the myocardial lesion is unknown but repeated administration of calcium salts has been suggested.[1] Downer cows with a poor prognosis also have greatly enhanced adrenocortical function.[10]

The prolonged recumbency can result in additional complications such as acute mastitis, decubitus ulcers, and traumatic injuries of the limbs.

The pathogenesis of the non-alert downer cow is not understood.[13] Most have had an initial episode of milk fever but do not respond satisfactorily. Within 1 or 2 days, affected cows have a preference for lateral recumbency and exhibit expiratory moaning and groaning. They represent about 2% of all cases of milk fever.

29.2.5.4.3

Experimental prolonged hypocalcemia

Experimental prolonged hypocalcemia may provide some clues about the pathogenesis of downer cow syndrome as a complication of milk fever. The prolonged infusion of ethylenediamine tetra-acetic acid (EDTA) in sheep over 18 h at a rate to induce hypocalcemia and maintain recumbency results in prolonged periods of recumbency, ranging from 36 to 64 h before the animals are able to stand.[14] There are also decreases in plasma sodium, plasma potassium, and erythrocyte potassium and prolonged increases in packed cell volumes, which suggests that fluid replacement therapy may be indicated in cattle with prolonged recumbency associated with hypocalcemia.[15] A 4-h IV infusion of EDTA in high erythrocyte potassium and low erythrocyte potassium dairy cows causes decreases in plasma inorganic phosphorus and plasma potassium which are still below normal 24 h later.[16] The AST, CPK, and PCVs and WBC counts are also elevated 24 h later. Plasma magnesium and erythrocyte sodium and potassium were decreased but this was delayed. The increase in PCV was most pronounced in the low erythrocyte potassium cows, which may provide some clues about the pathogenesis of downer cow syndrome. Some cows may have a more precipitate increase in PCVs due to loss of plasma volume and an inability to mobilize calcium. As a basis for studying the effects of hypertonic solutions to correct these abnormalities in downer animals, a 200 mL solution of 10 g of sodium chloride and 0.5 g of potassium chloride can be given IV to sheep safely over a period of 4–8 min.[17]

29.2.5.5

CLINICAL FINDINGS

The downer cow syndrome may occur independently, or follow apparent recovery after treatment for milk fever, except for the prolonged recumbency. In the typical case, affected cows either make no effort or are unable to stand following treatment for parturient paresis. About 30% of cows treated for milk fever will not stand for up to 24 h following treatment. Those which are unable to stand after 24 h and after two treatments are classified as downers. They are usually bright and alert and, although the appetite is reduced, the cow eats and drinks moderately well. The temperature is normal and the heart rate may be normal or elevated to 80–100 bpm. Tachycardia and arrhythmia occur in some cows, especially immediately following the administration of calcium IV and sudden death has occurred. Respirations are usually unaffected. Defecation and urination are normal but proteinuria is common and if marked may indicate extensive muscle damage.

Some affected cows may make no effort to stand. Others will make frequent attempts to stand but are unable to fully extend their pelvic limbs and lift their hindquarters more than 20–30 cm from the ground. These frequent attempts to stand result in ‘crawling' or ‘creeping' along the ground with both hindlegs in a partially flexed position and displaced posteriorly – the frogleg attitude. On a non-slippery surface (bare ground, sand pack, or deep bedding) some cows are able to stand with some assistance by lifting on the tail head or with the use of hip slings. Those cows which do not make an effort to stand usually cannot stand even with assistance and if supported with hip slings will usually make no effort to bear weight with either the hindlimbs or the forelimbs. Their limbs appear stiff, painful, or numb and they are unable or reluctant to bear weight. Damage to the peroneal nerve is usually present when there is hyperflexion of the fetlock joints, which is evident if and when the cow is able to stand and bear weight on the hindlimbs.

In some cases, the hindlimbs are extended on each side of the cow and reach up to the elbows on each side. In this position, the cow is bearing considerable weight on the medial thigh musculature and causing ischemic necrosis. This abnormal position of the legs may also be due to dislocation of one or both hip joints or associated with traumatic injuries surrounding the hip joints with or without rupture of the ligamentum teres. Regardless of the cause, the cow prefers this leg position and invariably will shift the legs back to the abnormal position if they are placed in their normal position.

In some cows, the signs may be more marked and bizarre, including a tendency to lie in lateral recumbency with the head drawn back. When placed and propped up in sternal recumbency, these cows appear almost normal but, when they are left alone, within a short period of time they revert to the position of lateral recumbency. Still more severe cases are hyperesthetic and the limbs may be slightly stiff but only when the cow is lying in lateral recumbency. These severe cases do not usually eat or drink, have been described as ‘non-alert downers', and are thought to have brain damage which has not been documented.[13] 1646 1647

Complications in the downer cow syndrome are common and often result in death or the need for euthanasia. Coliform mastitis, decubitus ulceration, especially over the prominences of the hock and elbow joint, and traumatic injuries around the tuber coxae caused by the hip slings are common. When these complications occur in the early stages of the disease, they commonly interfere with any progress being made and become the focus of clinical attention.

The course of the disease is variable and dependent on the nature and extent of the lesions and the quality of the care and comfort which is provided for the cow during the first few days. About 50% of downer cows will stand within 4 days or less if cared for properly. The prognosis is poor for those which are still recumbent after 7 days, although some affected cows have been down for 10–14 days and subsequently stood up and recovered. Death may occur in 48–72 h following the onset and is usually associated with myocarditis.

29.2.5.5.1

Clinical examination of the downer cow

Clinical examination of the downer cow can be very difficult and challenging depending on the environmental circumstances and the physical size of the animal. Many different metabolic, nutritional, musculoskeletal, toxic, neurological, neoplastic, inflammatory, and infectious diseases can cause recumbency in cattle.[18–20] It is very important to obtain an adequate history of the case on the first visit to the animal. Key aspects of the history include age of the animal, duration of recumbency, any previous clinical abnormalities before the recumbent stage such neurological in the case of bovine spongiform encephalopathy, or spinal cord lymphomatosis, any previous treatments with particular attention to mineralocorticoids which may cause hypokalemia, the anatomical location of any parenteral injections, time since recent parturition, diet and accidental access to new feeds, sudden unaccustomed exercise, and an assessment of the management provided.

The environment and the ground surface surrounding the recumbent animal may provide clues about the possibility that the animal slipped, fell, and was injured.

A systematic physical examination of all accessible body systems is necessary. The animal should be examined visually from a distance for evidence of abnormalities of the carriage of the head and neck, the position of the limbs, observe any attempts of the animal to stand or creep along the ground surface.

The details of the clinical examination are presented in Chapter 1. The standard close clinical examination is necessary to determine body temperature, heart rate and pulse, respiratory rate, and the state of the major body systems such as the respiratory tract, cardiovascular system, central nervous system for mental state, and gastrointestinal tract, mammary gland, reproductive tract, any of which may indicate the presence of abnormalities associated with shock which results in recumbency.

In the recently calved cow, particular emphasis must be given to adequate examination of the udder for mastitis, the uterus for metritis, and the gastrointestinal tract for diseases associated with toxemia and dehydration and shock (acute diffuse peritonitis, carbohydrate engorgement), which results in recumbency. A urine sample must always be obtained and tested for ketones, and the presence of myoglobinuria. A vaginal examination of the uterus should always be done along with a rectal examination.

Careful systematic examination of the musculoskeletal system includes palpating the muscles, bones, joints, and feet of each limb, including passive flexion and extension of each limb is necessary. The coxofemoral joints are examined for evidence of dislocation. The vertebral column is examined for evidence of painful sites or displacement of vertebrae. It is important to examine both sides of the animal which means rolling the cow over from side to side; often the animal may have to be rolled over more than once to repeat a particular examination.

A neurological examination includes examination of the withdrawal reflexes and sensation of all four limbs, reflex arcs of the spinal cord, careful examination of lumbar and sacral areas including sensation and tone in the tail, and examination of the cranial nerves.

The examination can be extended by lifting the downer cow with appropriate lifters and observing if the animal extends its limbs and attempts to bear weight. While the animal is being assisted to stand, additional examinations of other parts of the body can be made.

29.2.5.6

CLINICAL PATHOLOGY

The calcium, phosphorus, magnesium and glucose levels of the blood are within the normal range and the results of hematological examinations are usually consistent with those found in normal cows which have recently calved. The CPK and AST levels are usually markedly elevated by 18–24 h after the onset of recumbency and continue to elevate within the next few days. Continued elevation of CPK levels indicates continued muscle damage. In experimentally induced recumbency in cows, the CPK levels remained within normal limits for the first 6 h. However, by 12 h there was a marked increase to mean values of 12 000 U/L rising to 40 000 U/L by 24 h. There may be moderate ketonuria. A marked proteinuria is usually evident by 18–24 h after the onset of recumbency. The proteinuria may persist for several days or be absent within a few days.

In severe cases, the urine may be brown and turbid because of severe myoglobinuria. Low arterial blood pressures and abnormal electrocardiograms (ECGS) have been observed in some animals.

Elevations of serum urea, muscle enzymes, and laboratory evidence of inflammation are considered the best prognostic indicators of an unfavorable recovery.[4] The recovery rate was lower in cows with a total protein:fibrinogen ratio less than 10:1, and evidence of neutropenia and/or left shift.[4] Cows with a serum urea level above 25 mmol/L and serum creatinine levels above 130 mmol/L had a poor prognosis.

The CPK levels need to be interpreted in relation to the days of recumbency when the sample was taken. Critical levels may be highest initially (up to 50 times the upper normal reference range) and reduce to 10 times normal range at 7 days of recumbency.

In a series of 262 recumbent dairy cows serum samples were analyzed for creatine phosphokinase (CPK), lactate dehydrogenase (LDH) and aspartate aminotransferase (AST) to evaluate the value of serum enzyme activities for predicting a failure to recover.[21] The most common diagnosis was milk fever 61.1%, dystocia 11.1%, mastitis 8.4%, and trauma 6.9%. The prior probability of the cow not recovering was 0.24, 0.69, and 0.81 on days 1, 2, 3, and 4 of recumbency. The optimal cut-off points maximizing the sensitivity and specificity of the tests were 2330, 2225, and 171 U/L for CPK, LDH, and AST, respectively. The predictive value of AST was significantly better with optimal cut-off points of 128 and 189 U/L, respectively. AST provided the best predictive indicator of whether a recumbent cow would not recover, the best results being obtained with serum samples taken on the first day of recumbency.

1647

1648

29.2.5.7

NECROPSY FINDINGS

Hemorrhages and edema of the skin of traumatic origin are common. The major pathological changes consist of hemorrhages and degeneration of the medial thigh muscles. Hemorrhages around the hip joint with or without rupture of the ligamentum teres are also common. Local areas of ischemic necrosis of the musculature (gracilis, pectineus, and adductor muscles) occur at the anterior edge of the pelvic symphysis.[1] Eosinophilic infiltration of ruptured necrotic thigh muscles of downer cows has been described.[22] Hemorrhages and edema of the nerves of the limbs (obturator, ischiatic, peroneal, radial) are also common and usually associated with severe muscle damage. The heart is dilated and flabby and histologically, there is focal myocarditis. There is fatty degeneration of the

liver and the adrenal glands are enlarged. Histologically, there are also degenerative changes in the glomerular and tubular epithelium of the kidneys.

29.2.5.7.1

DIFFERENTIAL DIAGNOSIS

The diagnosis of downer cow syndrome is made after all other known causes of recumbency have been eliminated in a cow which had milk fever and failed to stand within 24 h following two successive courses of treatment. The other common causes of prolonged recumbency are described under the differential diagnosis of milk fever (Table 29.5). It is difficult and time consuming to examine a downer cow thoroughly to eliminate all other causes of recumbency. Only by repeated careful clinical examination will the clinician avoid the embarrassment of failing to detect the presence of coliform mastitis, a fractured leg or a dislocated hip.

29.2.5.8

TREATMENT

The prognosis of a downer cow depends on the cause of the recumbency and whether or not treatment is indicated or if euthanasia should be recommended because of the presence of abnormalities which are unlikely to respond favorably to treatment and also be economical. If the prognosis is poor, euthanasia on the farm should be recommended.

If the prognosis is favorable, the clinician should inform the owner about the nature of the treatment which will be necessary and its duration which may be several days of supportive care and therapy, and should outline the costs which will be incurred.

29.2.5.8.1

Fluid and electrolyte therapy

Many treatments including the injections of magnesium salts, phosphates, corticosteroids, stimulant tonics, and vitamin E and selenium have been used without consistent success. The use of parenteral solutions containing potassium, calcium, magnesium, and phosphorus has been recommended[10] but there is no scientific evidence that these electrolytes, in addition to what was probably given to the cow already, are indicated or are of any beneficial value. Large quantities of fluid and multiple electrolyte therapy by the oral or parenteral route is indicated for cows which may not be drinking normal quantities of water. Multiple electrolytes can be added to the drinking water if the cow is drinking normally.

29.2.5.8.2

Bedding and clinical care

The most important aspect of treatment is to provide the most comfortable bedding possible and to roll the cow from side to side several times daily to minimize the extent of ischemic necrosis and para-analgesia which results from prolonged recumbency. With conscientious care and the provision of good bedding, palatable feed and liberal quantities of water, most cows will attempt to stand with some difficulty and assistance within 24 h, and will stand unassisted and normally 1 or 2 days later. A sand or dirt pack is the ideal ground surface which facilitates standing when downer cows attempt to stand.[12] If affected cows are left on a slippery ground surface, they will not make an effort to stand and will become progressively worse. Cows should be milked normally and the udder kept clean by washing with germicide soap before milking, and post-milking teat dips applied.

29.2.5.8.3

Assisted lifting to aid standing

The clinician and farmer are commonly faced with the questions of whether or not to lift a recumbent cow which has not attempted to stand within a few hours after treatment for milk fever. The guiding principle should be the behavior of the cow. If the cow makes an effort to stand on her own or by some coaxing such as a gentle nudge in the ribs, she should be assisted to stand by insuring a good non-slip ground surface, deep bedding, and lifting up on the tailhead when she attempts to stand. The cow should be rolled from side to side every few hours and encouraged to stand a few times daily. With good clinical care, most cows with the uncomplicated form of downer cow syndrome secondary to milk fever will stand in 12–24 h.

29.2.5.8.4

Lifting devices

Several different kinds of cow-lifting devices have been used to assist downer cows to stand. Hip lifters, which fit and tighten over the tuber coxae, and body slings like harnesses are designed to fit around the abdomen and thorax of the animal. These devices can assist a downer cow to stand if she makes some effort on her own and it appears that ‘if she were given some help she could stand'. For those cows which make some effort to stand, the hip lifters or slings can be applied and the animal lifted to the standing position. If the animal bears weight on all four legs, she should be allowed to stand with the aid of the devices for 20–30 min and then lowered down. This procedure

should be repeated several times daily. In most cases, such downer cows will stand on their own within a few days. While the cow is in the standing position, she can be milked and other clinical examinations can be carried out.

The hip lifters can result in traumatic injuries to the tissues surrounding the tuber coxae if not used judiciously. Animals which make no effort to stand and bear weight on their own must not be left suspended in the lifter for more than a few minutes but lowered immediately. If the hip lifters are not applied carefully, the animal may slip out of the device while she is being lifted, which commonly results in tissue injury around the tuber coxae; fractures of the coxae have even occurred. These injuries are often unnoticed clinically, contribute to persistent recumbency and the true extent of the lesions are evident at necropsy. Lifting devices must be used carefully by experienced personnel.

Body slings which fit around the abdomen and thorax of the animal appear to be the ideal ‘animal lifter' because they distribute the weight over several sites in contrast to the hip lifters, which concentrate the weight over the tuber coxae. However, the body slings are cumbersome to apply to a recumbent animal, and require more time and experienced personnel to insure proper application. When the slings are applied properly, they do appear to allow the lifted animal to stand comfortably for 30 min or more and promote recovery.

Lifting cows which make no effort to stand on their own is usually unsuccessful. When lifted, they usually do not bear any significant weight.

A water flotation tank has been designed for the management of downer cows.[23] A prototype consists of a metal tub with inside dimensions of 92 in long, 43 in wide, and 51 in deep. The system is affordable, portable, durable, effective, and simple to use. The downer cow is pulled into the tub on a mat and the ends of the tub closed to make a water-tight container with an open top like a bath tub. With the cow's head held up by a halter, the tub is filled with water at 100–102°F as quickly as possible. Cows in lateral recumbency will roll into sternal recumbency when 12–24 in of water are in the container and will usually attempt to stand when the tub is one-half to two-thirds full. Cows are allowed to stand in the water for 6–8 h. If the water temperature falls below 95°F, more hot water is added. When the decision is made to remove the cow, the water is drained and the end of the tub opened, which allows the cow to walk out preferably onto a ground or grass surface. A success rate of 46% has been reported.[23] However, the success rate could be higher if the selection of cases for flotation are more rigorous. Cows with ruptured tendons, fractures, luxated coxofemoral joints, septic polyarthritis,

1648
1649

and other physical injuries of the musculoskeletal system are not good candidates for flotation. The most suitable case for flotation would appear to be the downer cow as a sequel to milk fever.

29.2.5.8.5

Handling, transportation, and disposition of non-ambulatory cattle

There has been considerable controversy and disparity among veterinarians and livestock producers about the handling, transportation, and disposition of non-ambulatory cattle.[24] Economics has a major influence on decision making in these cases. There has been no common understanding of whether or not they are fit for transportation and which ones are fit for slaughter for salvage. When the owner and veterinarian are faced with a downer cow which is valuable, and the cause of the recumbency is uncertain, the tendency is to either attempt to provide treatment for several days and assess the progress, or consider slaughter for salvage. In the case of valuable breeding animals which are recumbent as a complication of milk fever, or a disease such as acute carbohydrate engorgement, peracute mastitis, supportive, and specific therapy are commonly selected. In the case of downer cattle of commercial value, slaughter for salvage has been a common option. Cattle producers would like to obtain as much financial return as possible by slaughter for salvage. Cattle affected with complications of milk fever (ischemic necrosis of the pelvic limbs), traumatic injuries of the musculoskeletal system and other diseases not associated with toxemia or septicemia were commonly submitted to slaughter for salvage. Transportation of these compromised animals has always been an animal welfare issue because of the difficulty of loading them humanely because of their size. The mere act of lifting, pulling, dragging, and by other means of forcefully loading an animal weighing 500–800 kg onto a truck cannot be done without considerable pain and discomfort to the animal. However, beginning in the 1990s worldwide, concern emerged from the public about the handling and disposition of non-ambulatory animals particularly downer cows regardless of the cause of their recumbency. Government animal health regulatory agencies, livestock associations, and veterinary associations began drafting regulations on the care and handling of non-ambulatory recumbent animals like the downer cow.[24]

The downer cow syndrome is an animal welfare issue and the veterinarian should be proactive about the problem. Society is concerned about how downer animals are cared for and handled and the methods used for their disposition.[25] If recovery does not occur

within a few days the prognosis is uncertain and the owner and veterinarian must decide whether to continue providing clinical care to the downer cow or if the animal should be euthanized. In the USA in 1990–1992, 117 301 recumbent cattle were slaughtered at federally inspected abattoirs. Many consumers believe that meat derived from any non-ambulatory animal is unwholesome.

29.2.5.8.5.1

Disposition of downer cows in the USA

In December 2003, the US Department of Agriculture issued a ban on the slaughter and sale of non-ambulatory cattle for food. The ban applies to all states and at all federally-inspected slaughter plants.

29.2.5.8.5.2

Disposition of downer cows in Canada

In Canada, the Health of Animals Regulations states ‘no person shall load or cause to be loaded on any railway car, motor vehicle, aircraft, or vessel and no one shall transport or cause to be transported an animal (a) that by reason of infirmity, illness, injury, fatigue or any other cause cannot be transported without undue suffering during the expected journey'.

The Canadian Veterinary Medical Association's position statement regarding non-ambulatory livestock states: ‘If the animal is to be moved to a suitable processing facility, a veterinary inspection of the non-ambulatory animal must be performed on the premises of origin. The animal must be accompanied by an antemortem veterinary certificate declaring whether the animal can or cannot be humanely loaded, that the animal is fit for slaughter and that the owner has observed all applicable withdrawal times for drugs used. The loading and transportation of non-ambulatory animals must be performed in a manner to avoid pain, suffering and distress to the animal and upon arrival at the processing facility, the animal must be humanely stunned or euthanized on the vehicle prior to unloading. Equipment currently being used includes slide boards and mats, forklifts, front-end loaders, hand carts, slings, ‘cow caddys' and stone boats or sleds. In those situations where the non-ambulatory animal is passed for slaughter, but where the veterinarian deems loading and transportation inhumane, the Canadian Veterinary Medical Association recommends on-farm slaughter. Non-ambulatory animals deemed unfit for slaughter should be humanely euthanized on-farm and the carcass disposed of in accordance with local regulations'.[24]

In order to quantify the frequency of non-ambulatory cattle being transported to federally inspected slaughter plants and auction markets, the Canadian Food Inspection Agency conducted a national, non-statistical survey, focusing on inspection sites at 19 slaughter facilities and 3 auction markets across Canada.[24] These represent only a portion of all such federally inspected facilities. During the year 2001, 7382 non-ambulatory cattle were observed to arrive at these sites. Of this total, 89.8% were classified as dairy carcasses, while 10.2% were beef carcasses. The data strongly suggested that the vast majority of non-ambulatory animals originate on-farm, with less than 1% becoming non-ambulatory in transit or accidentally. Inspection led to carcass condemnation in 37% of non-ambulatory dairy animals.

In 2003, the Canadian Food Inspection Agency (CFIA) conducted stakeholder consultations on the evaluation of non-ambulatory livestock for fitness for transport. Stakeholder comments indicated that the small potential salvage value does not justify the animal suffering, human health hazards, reduced meat quality and negative impact on the image of the Canadian livestock industry that are associated with the loading of non-ambulatory livestock.

Most often, producers ship non-ambulatory livestock because they see no alternative – be it due to provincial restrictions, lack of inspectors, or missing infrastructure. Veterinarians have a professional responsibility to educate producers in the prevention, proper care, handling, and humane disposition of the non-ambulatory animal.

On 18 December, 2004 a proposal to amend the Health of Animals Regulations was published in Canada Gazette I. The proposed amendment would define a non-ambulatory animal as ‘an animal of the bovine, caprine, cervid, camelid, equine, porcine, or ratite species that is unable to stand without assistance or to move without being dragged or carried'. It would also clarify that:

- no person shall load or cause to be loaded on a conveyance or unload or cause to be unloaded a non-ambulatory animal for any purpose other than for transport for veterinary treatment or diagnosis on the advice of a veterinarian, and that

1649

1650

- non-ambulatory animal may be loaded on a conveyance or unloaded for purposes other than for veterinary treatment or diagnosis if the animal has first been rendered unconscious.

The Canadian Food Inspection Agency declared its Compromised Animals Policy, which is accessible at http://www.inspection.gc.ca/english/anima/heasan/transport/polie.shtml

29.2.5.8.5.2.1 Definitions used

29.2.5.8.5.2.1.1 Compromised animal.

An animal with reduced capacity to withstand the stress of transportation, due to injury, fatigue, infirmity, poor health, distress, very young or old age, impending birth, or any other cause. Some animals can be transported under certain conditions without being exposed to additional suffering. Others, such as non-ambulatory animals, animals with a body condition score indicating emaciation or weakness, or animals with severe lameness, would endure additional suffering during the transportation process and must not be transported except for veterinary treatment or diagnosis. This is true of any condition associated with pain that will be aggravated by transport.

29.2.5.8.5.2.1.2 Non-ambulatory animal.

'Non-ambulatory animal' means livestock or an animal that is unable to stand without assistance or to move without being dragged or carried, regardless of size or age. Non-ambulatory animals are also called 'downers'.

29.2.5.8.5.3 Disposition of downer cows in Europe

A proposed Council Regulation on the protection of animals during transport and related operations would define fitness for transport and ban the transport of animals deemed unfit. Animals that are injured or that present physiological weaknesses or pathological processes shall not be considered fit for transport. This includes animals that are unable to move independently without pain or to walk unassisted, and animals with severe open wounds. All member states of the EU would have to comply with the New Council Regulation. Access at: www.europa.eu.int/eur-lex/en/com/pdf/2003/com2003_0425en03.pdf

29.2.5.9

CONTROL

The early detection and treatment of milk fever will reduce the incidence and severity of downer cow syndrome. Under ideal conditions, cows should be treated during the first stage of milk fever before they become recumbent. Once recumbent, cows should be treated as soon as possible and not delayed for more than 1 h. Cows with milk fever should be well-bedded with liberal quantities of straw, or moved to a soft-ground surface. Recumbent cows should be coaxed and assisted to stand if possible after treatment for milk fever. If they are unable to stand, they should be rolled from one side to the other every few hours if possible. It is usually difficult to get owners to comply with this recommendation but frequent rolling from side to side is necessary to minimize the ischemic necrosis. Dairy cows should be placed in a comfortable well-bedded box stall prior to calving and should be left in that box stall until at least 48 h after partition in the event that milk fever develops.

29.2.6

ACUTE HYPOKALEMIA IN CATTLE

Hypokalemia in cattle may occur secondary to:

- Anorexia
- Diarrhea

- Upper gastrointestinal obstruction
- Right-sided displacement and torsion of the abomasum
- Impaction of the abomasum.

In most cases, the hypokalemia is not severe enough to cause weakness and recumbency.

Hypokalemia resulting in severe weakness and recumbency has occurred in dairy cattle treated with isoflupredone acetate for ketosis.[1] Serum potassium levels were below 2.3 mEq. Cows ranged in age from 2 to 7 years, all had a history of moderate to severe ketosis and had calved within the previous 30 days. Most had been also treated with insulin, IV glucose, and oral propylene glycol for the ketosis. However, not all cases have been treated with corticosteroids.[2,3] The disease has occurred in cattle of all age groups and a common history was the occurrence of a fever or infectious disease. Potential contributory factors to the development of significant hypokalemia in the chronically ketotic cow include reduced potassium intake subsequent to metabolic alkalosis and hyperglycemia, kaluresis resulting from hyperglycemic osmotic diuresis, and increased potassium loss from the mineralocorticoid effects of exogenously administered corticosteroids. Excessive use of corticosteroids with mineralocorticoid activity in cows with mastitis may also lead to hypokalemia.

Affected cows are recumbent, profoundly weak, appeared flaccid and lay in sternal or lateral recumbency. They are unable to support the weight of their heads off the ground and commonly hold them in their flanks. Profound weakness of the lateral cervical muscles may occur.[4] Anorexia is common. Cardiac arrhythmias are detectable on auscultation and atrial fibrillation is present on electrocardiography.

Treatment includes IV and oral administration of potassium chloride and fluid therapy but the response is commonly ineffective. Addition of potassium chloride to a 0.9% saline solution given as a continuous IV infusion at rates of up to 300 mmol of potassium per hour (approximately 0.4 mmol/kg per h) has been used in a 3-year-old cow. Oral supplementation with potassium chloride salt at 230 g, two to three times daily for 3 days was associated with recovery.[4] Palatable hay and propylene glycol orally are recommended. In a series of 14 cases, treatment consisted of potassium chloride given IV and orally at an average total daily dose of 42 g/100 kg BW (26 g orally and 16 g IV) for an average of 5 days, resulting in recovery in 11 cases after an average of 3 days.[3] During recumbency, affected cattle require special attention to minimize ischemic necrosis of muscles of the pelvic limbs.

At necropsy, muscle necrosis is present in the pelvic limbs and histological examination of non-weight bearing muscle reveal multifocal myonecrosis with microphage infiltration and myofiber vacuolation, which is characteristic of hypokalemic myopathy in man and dogs. It is important to note that myopathy is also present in muscles not subject to ischemia of recumbency.

Potassium excretion by the kidneys is via secretion by the distal tubular cells. Aldosterone or other steroids with mineralocorticoid activity enhance distal tubular secretion of potassium by increasing permeability of the tubular luminal membranes to potassium and increasing losses of potassium in the urine.

Glucocorticoids are often used to treat ketosis and the most commonly used are dexamethasone and isoflupredone acetate. Dexamethasone has little mineralocorticoid activity compared with prednisone and prednisolone, which are related chemically to isoflupredone. Dexamethasone is recommended for the treatment of ketosis in dairy cattle at a single dose of 10–20 mg IM, and repeated if necessary, 12–24 h later. Field observations indicate that repeated doses of isoflupredone acetate decrease plasma concentrations of potassium by 70–80%, which suggests a strong mineralocorticoid activity. It is recommended that isoflupredone be used judiciously and animals be monitored for plasma potassium and any evidence of weakness and recumbency. Treatment with oral potassium chloride may be required but treatment may be ineffective.

29.2.7

TRANSIT RECUMBENCY OF RUMINANTS

Transit recumbency (tetany) occurs after prolonged transport, usually in cows and ewes in late pregnancy. It is also recorded in lambs transported to feedlots,[1] and in cows,[2] and sheep[3] delivered to abattoirs. It is characterized by recumbency, alimentary tract stasis, and coma, and is highly fatal. It occurs in most countries. Large losses are encountered when cows and ewes in late pregnancy are moved long distances by rail, truck, or on foot.

Although cows of any age in late pregnancy are most commonly affected, the disease has also been recorded in cows recently calved, bullocks, steers, dry cows, and lambs. Risk factors include:

- Heavy feeding before shipment
- Deprivation of feed and water for more than 24 h during transit
- Unrestricted access to water
- Exercise immediately after unloading.

There is an increased incidence of the disease during hot weather. The cause is unknown, although physical stress is an obvious factor. In lambs there is:

- Restlessness
- Staggering
- Partial paralysis of hindlegs
- Early assumption of lateral recumbency.

Death may occur quickly, or after 2–3 days of recumbency. There is a mild hypocalcemia (7–7.5 mg/dL;1.75–1.87 mmol/L). The recovery rate even with treatment is only fair.

Clinical signs may occur while the cattle are still on the transportation vehicle or up to 48 h after unloading. In the early stages, animals may exhibit excitement and restlessness, trismus, and grinding of the teeth. A staggering gait with paddling of the hindlegs and recumbency occur, and are accompanied by stasis of the alimentary tract and complete anorexia. Animals that do not recover gradually become comatose and die in 3–4 days. There may be a moderate hypocalcemia and hypophosphatemia in cattle. In sheep of various ages, some are hypocalcemic and hypomagnesemic and some are hypoglycemic, but some have no detectable biochemical abnormality.[3] There are no lesions at necropsy other than those related to prolonged recumbency. Ischemic muscle necrosis is the most obvious of these lesions. The relationship of the disease to transport or forced exercise is diagnostic.

Some cases respond to treatment with combined calcium, magnesium, and glucose injections. Repeated parenteral injections of large volumes of electrolyte solutions are recommended. In lambs, the SC injection of a solution of calcium and magnesium salts is

recommended but the response is usually only 50%, due probably to an intercurrent myonecrosis.[4]

If prolonged transport of cows or ewes in advanced pregnancy is unavoidable, they should be fed on a moderately restricted diet for several days beforehand and provided with adequate food, water, and rest periods during the trip. The administration of an ataractic before loading is highly recommended, especially for nervous animals.[5] On unloading, they should be allowed only limited access to water for 24 h and should be allowed a minimum of exercise for 2–3 days.

29.2.8

LACTATION TETANY OF MARES (ECLAMPSIA, TRANSIT TETANY)

Lactation tetany of mares is caused by hypocalcemia and is characterized by abnormal behavior progressing to incoordination and tetany. The precise cause of the hypocalcemia has not been determined, but the cause of the clinical signs is a marked reduction in serum concentration of ionized calcium. The effect of feeding diets high in calcium, such as alfalfa hay, during late pregnancy, and of abrupt changes in diet after parturition, have not been investigated in horses as they have in cattle (see Milk fever).

The disease was most common when draft horse breeding was widely practiced but is uncommon now. The mortality rate is high in untreated animals. Most cases occur in lactating mares, either at about the 10th day after foaling or 1–2 days after weaning. High-producing mares grazing on lush pasture are most susceptible and in many instances are engaged in hard physical work. The housing of wild ponies, or prolonged transport may precipitate an episode. The latter has been a particularly important factor in the etiology of the disease in Britain and has been credited with precipitating it even in stallions and dry mares. Occasional cases occur without there being any apparent cause.[1] The disease has

occurred in a 20-year-old gelding pony.[2] Hypocalcemia with clinical signs also occurs in horses used for prolonged exercise, such as endurance racing or 3 day eventing.[3]

Many mild cases which recover spontaneously occur after transport but the mortality rate in some shipments may be greater than 60%. Mares that develop the disease at the foal heat or at weaning are usually more seriously affected and the mortality rate is high if mares are not treated in a timely fashion.

Severely affected animals sweat profusely and have difficulty in moving because of tetany of the limbs and incoordination. The gait is stiff and the tail is slightly raised. Rapid, labored respirations and wide dilatation of the nostrils are often accompanied by synchronous diaphragmatic flutter (‘thumps') evident as a distinct thumping sound from the thorax. Muscular fibrillation, particularly of the masseter and shoulder region, and trismus are evident but there is no prolapse of the membrana nictitans.[4] Affected animals are not hypersensitive to sound but handling may precipitate increased tetany. The temperature is 1651
normal or slightly elevated, and although the pulse is normal in the early stages, it later 1652
becomes rapid and irregular. The mare may make many attempts to eat and drink but appears to be unable to swallow and passage of a stomach tube can be difficult. Urination and defecation are in abeyance, and peristalsis is reduced.

Within about 24 h the untreated mare becomes recumbent, tetanic convulsions develop and become more or less continuous; the mare dies about 48 h after the onset of illness. The tetany and excitement in the early stages may suggest tetanus but there is no prolapse of the third eyelid and there is the usual relationship to recent foaling or weaning and physical exertion. The anxiety and muscle tremor of laminitis may also be confused with those of lactation tetany, especially as it may occur in mares which have foaled and retained the placenta. Pain in the feet is the diagnostic feature of this latter disease.

Hypocalcemia occurs with serum levels in the range of 4–6 mg/dL (1–1.50 mmol/L) and the degree of hypocalcemia has been related to the clinical signs.[5] When serum calcium levels are higher than 8 mg/dL (2 mmol/L) the only sign is increased excitability. At levels of 5–8 mg/dL (1.25–2 mmol/L) there are tetanic spasms and slight incoordination. At levels of less than 5 mg/dL (1.25 mmol/L), there is recumbency and stupor. It is the concentration of ionized calcium that is important and some animals, such as horses used for 3 day eventing, can have normal total calcium concentrations but abnormally low ionized calcium concentrations as a result of changes in acid:base status. If possible, serum concentrations of ionized calcium should be measured in horses with clinical signs suggestive of

hypocalcemia. Hypomagnesemia with serum magnesium levels of 0.9 mg/dL (0.37 mmol/L) has been observed in some cases but only in association with recent transport. Hypermagnesemia has been reported in other cases.

Treatment by IV administration of calcium borogluconate as recommended in the treatment of parturient paresis in cattle results in rapid, complete recovery. The dose for a 500 kg mare is 300–500 mL of a 25% solution of calcium borogluconate or gluconate administered slowly (over 15–30 min) intravenously. One of the earliest signs of recovery is the voiding of a large volume of urine. Occasional cases which persist for some days are recorded.

29.2.9

HYPOMAGNESEMIC TETANIES

Tetany associated with depression of serum magnesium levels is a common occurrence in ruminants. The syndrome associated with hypomagnesemia is relatively constant, irrespective of the cause, but the group of diseases in which it occurs has been divided into hypomagnesemic tetany of calves, which appears to be due specifically to a deficiency of magnesium in the diet, and a group of hypomagnesemias in ruminants characterized by lactation tetany, in which there may be a partial dietary deficiency of magnesium but in which nutritional or metabolic factors reduce the availability, or increase the body's loss, of the element so that serum magnesium levels fall below a critical point. In general, the occurrence of hypomagnesemic tetany is related to three sets of circumstances. Most common is the occurrence in lactating cows turned out on to lush, grass-dominant pasture in the spring after wintering in closed housing – the classic lactation or grass tetany of Holland. Wheat pasture poisoning may occur when any type of cattle or sheep is grazed on young, green cereal crops. The third occurrence is in beef or dry dairy cattle running at pasture in the winter, usually when nutrition is inadequate and where no shelter is provided in changeable weather rather than in severe, prolonged cold. Less common forms occur in housed animals on poor feed. Hypomagnesemia of sheep, although it is less common, occurs in the same

general groups of circumstances as the disease in cattle. A chronic hypomagnesemia, without manifestations of tetany, can be a cause of suboptimal production efficiency and may predispose to hypocalcemia.

29.2.10 HYPOMAGNESEMIC TETANY (LACTATION TETANY, GRASS TETANY, GRASS STAGGERS, WHEAT PASTURE POISONING)

29.2.10.1 Synopsis

29.2.10.1.1 Etiology

The etiology is multifactorial, related to magnesium concentration in the diet and the presence of competing cations such as potassium and sodium that affect either herbage magnesium status or magnesium absorption.

29.2.10.1.2 Epidemiology

Disease of all classes of ruminants but reaches its highest incidence in older lactating cows exposed to bad weather or grazing green cereal crops or lush grass-dominant pasture.

29.2.10.1.3 Clinical findings

Incoordination, hyperesthesia and tetany, tonic–clonic muscular spasms and convulsions. High case fatality without treatment.

29.2.10.1.4 Clinical pathology

Serum, urine, or cerebrospinal fluid (CSF) magnesium concentrations. Hypomagnesemia, and in some circumstances hypocalcemia.

29.2.10.1.5 Necropsy findings

None specific.

29.2.10.1.6 Diagnostic confirmation

Response to treatment, serum or urinary magnesium concentrations.

29.2.10.1.7

Treatment

Magnesium or combined calcium/magnesium solutions administered IV and/or SC.

29.2.10.1.8

Control

Magnesium supplementation but a palatable and practical delivery method is a problem. Magnesium applied to pastures. Avoidance of movement and food deprivation at risk periods.

29.2.10.2

ETIOLOGY

Magnesium is the major **intracellular divalent cation**, and is an essential element in a large number of enzymic activities in the body. For this reason it might be expected that hypomagnesemia would be rare. However, because of the peculiarities of absorption of magnesium in the ruminant forestomachs, and the use of animal and pasture management systems that can lead to marginal magnesium uptake, ruminants are at risk of hypomagnesemia.

29.2.10.2.1

Magnesium homeostasis

There is **no feedback regulatory mechanism** to control concentrations of magnesium in the body of ruminants. As a consequence, magnesium concentrations in blood and extracellular fluid are essentially determined by the balance between dietary intake of magnesium, loss in feces and milk, and the modulating effect of magnesium **homeostasis by the kidney**.[1]

29.2.10.2.1.1

Dietary intake

In normal circumstances, magnesium absorbed from the diet is sufficient to meet the requirements of the body and excess amounts are excreted in the urine.

29.2.10.2.1.2

Renal excretion

The kidney is the major organ of homeostasis and can act to conserve magnesium. Magnesium is freely filtered across the renal glomerulus and is reabsorbed within the renal tubules, the degree of reabsorption acting in homeostasis. When the dietary intake of magnesium is decreased, blood and interstitial fluid magnesium

concentrations fall; excretion of magnesium in the urine will cease when **serum concentrations fall below 1.8 mg/dL**. The renal threshold for magnesium excretion is partially under the control of parathyroid hormone and increased levels of parathyroid hormone will act to conserve magnesium.

29.2.10.2.1.3

Magnesium reserves

1652

1653

There are large stores of magnesium in the body, especially in bone. These are available to the young calf but mobilization decreases with age and in the adult ruminant there is little mobilization in response to short-term deficits of magnesium.[1] In ruminants, this control mechanism for magnesium can maintain adequate concentrations of magnesium in bodily fluids in most production circumstances but it can fail where there is a high requirement for magnesium coupled with a decreased intake. This combination leads to hypomagnesemia and hypomagnesemic tetany is a possible outcome.

29.2.10.2.1.4

Lactation

Increased requirement for magnesium is almost always associated with the loss of magnesium in the milk during lactation. Whereas the amount of magnesium in milk is not high (12 mg/kg) the loss of magnesium to milk represents a significant proportion of the dietary intake of magnesium. As a consequence of this drain, most instances of hypomagnesemia occur in lactating animals around the period of peak milk production, although in some circumstances the demands of late pregnancy are the cause of the increased requirement. The decreased intake of magnesium can result from an absolute deficiency of magnesium in the diet or because the availability or absorption of magnesium from the diet is impaired. These factors determine the circumstances of occurrence of the disease and are the **factors that can be manipulated for control**.

29.2.10.2.2

Factors influencing absorption of magnesium

In the adult ruminant, magnesium absorption occurs in the forestomach with little absorption in the abomasum and small intestine. Some absorption occurs in the large intestine, particularly in sheep,[2] however it cannot compensate for malabsorption in the forestomach.

29.2.10.2.2.1

Na:K ratio in rumen

Magnesium is transported across the epithelium of the forestomachs by an active sodium-linked ATPase-dependent transport system. Absorption, and the serum magnesium concentration, is influenced by the Na:K ratio in the rumen, which is determined by the dietary and salivary concentrations of sodium and potassium.[3,4] Absorption of magnesium increases with an increasing Na:K ratio to plateau at a ratio of 5:1. Absorption is significantly impaired if the Na:K ratio is less than 3:1.

Young rapidly growing grass is low in sodium and high in potassium, can result in **sodium deficiency** in ruminants that graze it, and can significantly depress the Na:K ratio in the rumen fluid, causing impairment of magnesium absorption. Depression is observed at dietary potassium concentrations of greater than 22 g/kg dry matter.

Saliva normally has a high Na:K ratio but where there is a deficit of sodium in the diet, a proportion of sodium in saliva may be replaced with potassium under the influence of aldosterone, which further negatively influences the uptake of magnesium.

Approximately 40% of the total magnesium available in extracellular fluid is secreted daily in saliva and 20% of this is reabsorbed in the forestomach. When animals are on tetany-prone grass, this absorption is impaired, which accounts for the susceptibility of ruminants to hypomagnesemia compared with monogastric animals.[3]

29.2.10.2.2.2

Other factors influencing absorption

Young grass fertilized with nitrogenous fertilizers has an increased crude protein which is readily fermentable and leads to increased ammonia concentrations. A sudden rise in ruminal concentrations of ammonia impairs magnesium absorption in the rumen.[5,6] The uptake of magnesium is also influenced by the carbohydrate content of the diet, magnesium absorption is improved with increasing amounts of readily degradable carbohydrates.[7] The mechanism of this action is not known but low concentrations of readily degradable carbohydrate in tetany-prone pastures in combination with high concentrations of protein may be important to the occurrence of the syndrome.[5] Volatile fatty acids provide the energy for the active transport of magnesium across the rumen wall and increase magnesium absorption.

Other dietary substances have been proposed to influence the absorption of magnesium including calcium and phosphorus, organic acids such as citric acid and transaconitate, fatty acids, and aluminum, but the significance of their role is controversial.[5]

29.2.10.2.3

Magnesium in pastures and tetany hazard

The dietary intake of magnesium in grazing animals is directly related to the magnesium concentration in pastures but other elements in pastures also influence magnesium absorption by the ruminant as detailed earlier.

29.2.10.2.3.1

Required magnesium concentrations

Hypomagnesemia can result from the ingestion of pastures that have insufficient magnesium to meet dietary requirements. The estimated magnesium concentration in pasture required to meet the dietary requirement for pregnant or lactating cattle varies from 1.0 to 1.3 g/kg dry matter (DM) for pregnant cattle, depending upon the stage of pregnancy, and 1.8–2.2 g/kg DM for lactating cattle with both estimates assuming minimal interference of absorption by other elements in the pasture.[8]

The recommended minimal ‘safe' concentration of magnesium in pastures is 2 g/kg DM for lactating and pregnant cattle with a preference for a concentration of 2.5 g/kg DM.

29.2.10.2.3.2

Magnesium availability in pastures and hazard

Hypomagnesemia can also occur in animals grazing pastures with adequate concentrations of magnesium but that contain high concentrations of potassium and nitrogen, which as detailed earlier, impair absorption of magnesium in the rumen. Pastures with concentrations of **potassium** of greater than 30 g K/kg DM and **nitrogen** greater than 40 g N/kg dry matter are considered hazardous.

An alternate method for estimating the potential **hazard of a pasture** is to calculate the **K/(Ca + Mg) ratio** using milliequivalent (mEq) values for this estimate. Pastures with ratios above 2.2 are considered a risk.[9]

29.2.10.2.4

Winter hypomagnesemia

The occurrence of hypomagnesemia is not restricted to cattle grazing lush pastures and it also occurs in the winter periods. In **housed lactating dairy** cattle being fed conserved feeds, hypomagnesemia probably has the same genesis as that in grazing cattle being associated with a high lactational drain of magnesium in combination with the feeding of conserved feeds prepared from pastures with marginal magnesium concentrations. It also occurs in **cattle outwintered** on poor quality feed.

29.2.10.2.5

Hypomagnesemia and hypocalcemia

In some outbreaks of hypomagnesemic tetany, there is also hypocalcemia and, although it is of less severe degree than in parturient paresis, there is increasing evidence that the actual onset of clinical tetany may be associated with a rapid fall in serum calcium levels superimposed on a pre-existing hypomagnesemia. This is particularly true for wheat pasture poisoning but can also apply to outbreaks with different predisposing factors.

Chronic hypomagnesemia can have a profound effect on calcium homeostasis. Hypomagnesemia reduces the production and secretion of parathyroid hormone, reduces hydroxylation of vitamin D in the liver, and also causes target organ insensitivity to the physiological effects of parathyroid hormone and 1,25-dihydroxyvitamin D_3.[6,10,11] Chronic subclinical hypomagnesemia can increase susceptibility to milk fever and can predispose to episodes of **milk fever and downer cows in lactating dairy cows** during the period of peak lactation. 1653 1654

29.2.10.2.6

Summary of etiology

In summary, it appears that a number of factors are capable of causing hypomagnesemia in ruminants and that under particular circumstances one or other of them may be of major importance.

In lactation tetany of cows and ewes turned on to lush pasture in the spring, a primary dietary deficiency of magnesium or the presence of high relative concentrations of potassium and nitrogen in the diet reduces the absorption of magnesium and possibly calcium.

In wheat (cereal) pasture poisoning, the ingestion of abnormally large amounts of potassium and low levels of calcium in the diet leads to hypomagnesemia and also hypocalcemia.

Hypomagnesemic tetany in cattle wintered at pasture and exposed to inclement weather is associated with low magnesium intake and inadequate caloric intake, and possibly to the resultant hyperactivity of the thyroid gland.

Although the above suggestions as to the most important etiological factors in each set of circumstances in which lactation tetany occurs may be valid, undoubtedly **combinations** of these and other factors have etiological significance in individual outbreaks of the disease. The **worst combination** of causative factors, and the most common circumstances in which the disease occurs, is inadequate energy intake with a low dietary content of magnesium (grass pasture) in recently calved cows during a spell of cold, wet, and especially windy weather.

One other important factor is the **variation between individual animals in susceptibility** to hypomagnesemia and to the clinical disease. These variations are quite marked in cattle and in intensively managed, high-producing herds it is probably worthwhile to identify susceptible animals and give them special treatment.[12]

29.2.10.3

EPIDEMIOLOGY

29.2.10.3.1

Occurrence and risk factors for lactation tetany

Lactation tetany in dairy and beef cattle turned out to graze on lush, grass dominant pasture after winter housing is common in northern Europe, the UK, and the northern parts of North America. Grass tetany also occurs in Australia and New Zealand, where the cows are not housed in winter but have access to a phenomenal flush of pasture growth in the spring.[13] This also commonly occurs in beef cattle in all countries.

With housed cattle, or cattle fed conserved feed during the winter, most cases occur during the first 2 weeks after the cattle are turned out to **spring pasture**. Pasture which has been heavily topdressed with fertilizers rich in nitrogen and potash is potentially the most dangerous. The disease may also occur on this type of pasture even when the cattle have wintered on pasture in temperate regions. In regions where there is an autumn flush

of pasture, a high incidence of hypomagnesemic tetany may occur in the **autumn** or early winter.

Cattle in the **first 2 months of lactation** and **4–7 years of age** are most susceptible, which probably reflects an increased risk due to a higher loss of magnesium in milk. **Friesian** cows have lower magnesium concentrations than Jerseys grazed under the same conditions.[14]

In the northern parts of the USA, outbreaks commonly occur during periods of **low barometric pressure** when the **ambient temperature** ranges between 7°C (45°F) and 15.5°C (60°F) and **soil temperatures** are below 7°C (45°F). Outbreaks may be precipitated by inclement weather. In beef cattle there is commonly a history of poor nutrition and falling body condition in the past few weeks due to diminishing hay supplies.

29.2.10.3.2

Occurrence and risk factors for wheat (cereal) pasture poisoning

Wheat pasture poisoning is a misnomer as it can occur with grazing of any small-grain cereal pasture. It has been recorded in many countries but is most prevalent where **young cereal crops** are utilized for ‘winter grazing'. The southwestern USA has experienced heavy losses of cattle caused by this disease. This pasture can induce hypomagnesemia in **pregnant and lactating cattle and sheep**. The risk is with young rapidly growing pasture, either in the **spring**, or in the **autumn and winter** with pastures planted in late summer. The pasture is usually dangerous for only a few weeks but heavy losses may occur in all classes of sheep and cattle. *Bos taurus* breeds are more susceptible to the development of hypomagnesemia than *Bos indicus*.[15]

29.2.10.3.3

Occurrence and risk factors for winter hypomagnesemia

Hypomagnesemic tetany in cattle wintered in the open causes some losses in the UK, New Zealand, southern Australia, and the east-central states and Pacific slope of the USA. It occurs in cattle grazed on pasture in the winter with **minimal supplemental hay** and in cattle grazed on **aftermath crops** and corn stover. The disease occurs in regions with temperate climates, and risk is increased by **exposure to bad weather**, which is exacerbated by absence of trees or other **shelter** in fields and by failure to supply supplementary feed during these cold spells. The disease does not seem to occur in cattle kept outside in prolonged winters where environmental temperature is consistently very low and there is adequate feed. Hypomagnesemia, commonly presenting as chronic

hypomagnesemia and sudden death, has been recognized as occurring in housed cattle in the winter in Europe for many years and recently has also been reported in the USA.

29.2.10.3.4

Morbidity and mortality

In all of these forms of the disease, the morbidity rate is highly variable, reaching as high as 12% in individual herds, and up to 2% in particular areas. The incidence varies from year to year depending largely on climatic conditions and management practices, and the disease is often limited in its occurrence to particular farms and even to individual fields.

Although an effective treatment is available, the **case-fatality rate is high** because of the short course. Since animals die before they are observed to be ill, there are not accurate figures on case fatality, but it is probably of the order of 30% in dairy cattle and considerably higher in beef cattle.

There have been few epidemiological studies specifically addressing the importance of the syndrome. In Finland, a **lactational incidence rate** varying between 0.1% and 0.3% is recorded, with an **increase in parity** to at least six for lactation tetany occurring on pasture but not for indoor tetany.[15] No association with other diseases was found other than for milk fever. In Northern Ireland, approximately 10% of dairy cows and 30% of beef cows have subnormal or deficient blood magnesium concentrations during the grazing season and hypomagnesemia is considered the cause of 20% of the ‘sudden death' mortality in beef cattle.[16,17] Surveys of beef cattle owners of the relative importance of different diseases invariably rate hypomagnesemia high in importance.

29.2.10.3.5

Pasture risk factors

In most areas of the world, there is a strong association between risk for hypomagnesemia and systems of pasture improvement and pasture fertilization to increase forage yield. There are a number of influences on the concentration of magnesium and other elements in pasture.

29.2.10.3.5.1

Pasture species

Hypomagnesemia is a problem on grass-dominant pastures. Concentrations of calcium and magnesium are higher in legumes and forbs than in grasses. Within the grasses, different genotypes of the same species can differ markedly in calcium and magnesium concentrations and most **cool season grasses** have the potential to produce

hypomagnesemia. However, there are some differences and grasses with a high ratio of potassium to calcium and magnesium (e.g. *Dactylis glomerata*, *Lolium perenne*, *Phalaris arundinacea*) are more likely to cause grass tetany than those with low ratios (e.g. *Bromus inermis*, *Poa pratensis*, *Agrostis* spp.).[9] On soil types where the disease is common, cool-season grass pastures top-dressed with **nitrogenous fertilizers** are dangerous and their toxicity may be increased by the **application of potash**. **Warm-season grasses** do not have the same risk and grass tetany is not a problem in cattle grazing tropical grasses.

29.2.10.3.5.2

Cereal pastures

The greater tendency of cereal grazing to cause hypomagnesemia, is related to a high content of potassium as well as a low content of magnesium. Tetany hazard, in order of decreasing hazard, is wheat, oats, barley, rye.[14]

29.2.10.3.5.3

Season

High concentrations of potassium and nitrogen and low concentrations of sodium and soluble carbohydrates occur in pastures during the early growing season and during rapid growth following cold, wet periods. Pasture magnesium concentrations may not be depressed but the K/(Ca + Mg) ratio is increased.[18]

29.2.10.3.5.4

Fertilization

Application of potash and nitrogenous fertilizers to pastures will decrease the concentration of calcium and magnesium in plants and will also increase the concentration of potassium and nitrogen. There is some evidence that nitrate sources of nitrogen depress magnesium less than ammonium sources of nitrogen.

29.2.10.3.5.5

Soil type

The availability of magnesium to the plant is influenced by soil type and some deficiencies in plant magnesium can be corrected by soil fertilization with magnesium.[19] There is no strong association with any one soil type but high potassium concentrations are consistently associated with increased risk for tetany.

Highly leached, acid, sandy soils are particularly magnesium deficient and the most likely to respond to liming and magnesium fertilization.[8] In very acidic soils, high aluminum concentrations may depress magnesium uptake by plants.

A local knowledge of soil type and its influence on magnesium, potassium, calcium, and nitrogen uptake by pastures can allow the judicious selection or avoidance of the use of pastures for at-risk groups during periods of risk for hypomagnesemia.[12]

29.2.10.3.6

Animal and management risk factors

29.2.10.3.6.1

Dry matter intake

The dry matter and energy intake of ruminants can influence susceptibility to hypomagnesemia.[20] A reduction in dry matter intake must reduce the magnesium intake and, in situations where hypomagnesemia is already present, a further depression of serum magnesium levels can be anticipated when complete or partial starvation occurs. An insufficient intake of **fiber** in the winter months can precipitate hypomagnesemia in pastured cows and ewes and lipolysis is accompanied by a fall in serum magnesium.

29.2.10.3.6.2

Period of food deprivation

Many outbreaks of hypomagnesemia are preceded by an episode of stress or temporary starvation. Whether chronic hypomagnesemia pre-exists or not, a period of starvation in lactating cows and ewes is sufficient to produce a marked hypomagnesemia and the fall may be sufficiently great to cause clinical tetany. A period of **bad weather, yarding, transport, or movement** to new pastures or the introduction to **unpalatable pastures** may provide such a period of partial starvation.

29.2.10.3.6.3

Alimentary sojourn

Diarrhea is commonly associated with lactation tetany on spring pasture and by decreasing the alimentary sojourn may also reduce magnesium absorption.

29.2.10.3.6.4

Climate

A close association between climatic conditions and serum magnesium levels has also been observed. Reduced levels occur in adult cattle and sheep exposed to cold, wet, windy weather with little sunshine and no access to shelter or supplementary feed. Supplementary feeding appears to reduce the effect of inclement weather on serum magnesium levels and it is possible that failure to eat, or depression of appetite, and a negative energy balance during bad weather may be a basic contributing cause to hypomagnesemia in these circumstances.

29.2.10.3.7

Animal movement

Epinephrine release will result in a precipitous fall in serum magnesium and this may explain the common observation that clinical cases are often precipitated by excitement or movement of the herd.

29.2.10.3.7.1

Intensive dairies

Intensive dairies that apply effluent on a limited land base can build soil potassium to high concentrations. Silage from these grounds can have a high risk for inducing hypomagnesemia.

29.2.10.3.8

Hypomagnesemia in sheep

Hypomagnesemia occurs in sheep, particularly in Australia and the United Kingdom. The disease is not common but appears to be increasingly associated with pasture improvement practices, and can cause heavy losses in individual flocks. It is more common in ewes bred for milk and lamb production. In outbreaks, **ewes with twins** are more liable to develop clinical disease than those with singles and the main occurrence is in ewes **1–4 weeks after lambing** with cases up to 8 weeks after lambing.

Disease is often precipitated by a **management procedure** involving movement and temporary food deprivation and cases will occur within the first 24 h following this and for a few days afterwards. As in cattle, disease occurs when ewes are placed on lush grass pastures but it is especially common where ewes in early lactation are placed on young cereal pastures. Losses usually cease when the flock is moved onto rough, unimproved pasture.

Cases also occur in sheep which are exposed to inclement weather when on low nutritive intake. Simultaneous hypomagnesemia and ketosis can occur in ewes after lambing if they are exposed to low feed availability. These cases do not respond well to treatment. Hypomagnesemia in ewes is predisposed by **prior pregnancy toxemia** in the flock.

29.2.10.4

PATHOGENESIS

Most evidence points to hypomagnesemia as the cause of the tetanic signs observed but the concurrent hypocalcemia may have a contributory effect and in many instances may even be the dominant factor. Most clinical cases of the disease have serum magnesium levels below 1 mg/dL (0.41 mmol/L) compared with the normal levels in cattle of 1.7–3 mg/dL (0.70–1.23 mmol/L) and there is a striking relationship between the incidence of the clinical disease and the occurrence of a seasonal hypomagnesemia.

The reduction in serum levels of magnesium is concurrent with a marked fall in the excretion of magnesium in the urine. In affected herds and flocks, many clinically normal cows and sheep have low serum magnesium levels. In some of these circumstances a concurrent hypocalcemia may be the precipitating cause.

Magnesium has many influences on impulse transmission at the neuromuscular system, including effects on the release of acetylcholine, on the sensitivity of the motor end plate, on the threshold of the muscle membrane and on activation of the cholinesterase system. These offer an attractive hypothesis for the muscular irritability seen with the disease. However, it has also been established that magnesium concentrations in the cerebrospinal fluid are more predictive of clinical disease than those in serum, which would indicate that alterations in CNS function are more important than alterations in peripheral nerve function. It is also evident that CSF levels of magnesium in hypomagnesemic animals rise significantly after treatment with a magnesium salt.[21] The need for this to happen would explain the delay of about 30 min after an IV injection before recovery occurs.

1655

1656

29.2.10.5

CLINICAL FINDINGS

For convenience, lactation tetany is described in acute, subacute and chronic forms.

29.2.10.5.1

Acute lactation tetany

The animal may be grazing at the time and suddenly cease to graze, adopt a posture of **unusual alertness** and appear uncomfortable; twitching of the muscles and ears is also

evident. There is severe **hyperesthesia** and slight disturbances precipitate attacks of continuous bellowing, frenzied galloping, and occasionally aggression. The gait becomes **staggering** and the animal falls with obvious tetany of the limbs, which is rapidly followed by **clonic convulsions** lasting for about a minute. During the convulsive episodes there is:

- Opisthotonos
- Nystagmus
- Champing of the jaws
- Frothing at the mouth
- Pricking of the ears
- Retraction of the eyelids.

Between episodes, the animal lies quietly but a sudden noise or touch may precipitate another attack.

The temperature rises to 40–40.5°C (104–105°F) after severe muscle exertion; the pulse and respiratory rates are also high. The absolute intensity of the heart sounds is increased so that they can be heard some distance away from the cow. Death usually occurs within 5–1 h and the mortality rate is high because many die before treatment can be provided. The response to treatment is generally good if the animal is treated early.

29.2.10.5.2

Subacute lactation tetany

In this form of the disease, the onset is more gradual. Over a period of 3–4 days, there is slight inappetence, **wildness of the facial expression** and **exaggerated limb movements**. The cow often resists being driven and throws her head about as though expecting a blow. **Spasmodic urination** and frequent defecation are characteristic. The appetite and milk yield are diminished and ruminal movements decrease. **Muscle tremor** and mild tetany of the hindlegs and tail with an unsteady, straddling gait may be accompanied by retraction of the head and trismus. Sudden movement, noise, the application of restraint or insertion of a needle may precipitate a violent convulsion.

Animals with this form of the disease may recover spontaneously within a few days or progress to a stage of recumbency with a similar but rather milder syndrome than in the acute form. Treatment is usually effective but there is a marked tendency to relapse.

29.2.10.5.3

Chronic hypomagnesemia

Many animals in affected herds have low serum magnesium levels but do not show clinical signs. There may be sudden death.[22] A few animals do evidence a rather vague syndrome including dullness, unthriftiness and indifferent appetite and may subsequently develop one of the more obvious syndromes. In lactating cows, this may be the development of paresis and a milk fever-like syndrome that is poorly responsive to calcium treatment. Depressed milk production has also been attributed to chronic hypomagnesemia in dairy herds in New Zealand.[23] The chronic type may also occur in animals which recover from the subacute form of the disease.

29.2.10.5.4

Parturient paresis with hypomagnesemia

This syndrome is described under parturient paresis and consists of paresis and circulatory collapse in an adult cow which has calved within the preceding 48 h but in which dullness and flaccidity are replaced by hyperesthesia and tetany.

29.2.10.6

CLINICAL PATHOLOGY

Serum or urinary magnesium concentrations can be used for clinical cases. Where an animal is dead and hypomagnesemia is suspect, a presumptive diagnosis can be made from samples taken from other at-risk animals in the group, or from the vitreous humor of the dead animal. An acute phase inflammatory response with leukocytosis and increased numbers of neutrophils and monocytes has been recorded in ruminants and laboratory animals fed magnesium deficient diets.[24]

29.2.10.6.1

Serum magnesium concentrations

Normal serum magnesium concentrations are 1.7–3 mg/dL (0.70–1.23 mmol/L). These levels in cattle are often reduced in seasonal subclinical hypomagnesemia to between 1 and 2 mg/dL (0.41 and 0.82 mmol/L) but risk for tetany is not present until the level falls to below 1.2 mg/dL (0.49 mmol/L).

The average level at which signs occur is about 0.5 mg/dL (0.21 mmol/L) and in sheep it is suggested that clinical tetany does not occur until the serum magnesium level is below 0.5 mg/dL (0.21 mmol/L).
